Cardiac pacing

Francisca Caetano and Brijesh Vipinchandra Patel

Cardiac pacing is an important part of electrophysiology and of cardiology in general. Nevertheless, intensive care physicians should be familiar with such devices, as there is a continuous growth in the use of implanted cardiac electronic devices due to the increasing life expectancy and ageing of populations. [1]

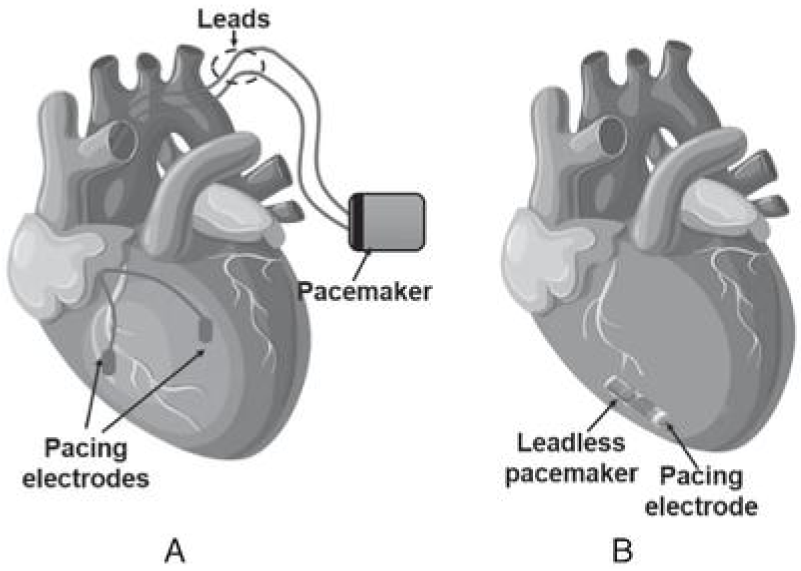
Cardiac pacing has rapidly evolved since its introduction by Zoll in 1952. [2] Whereas some of the situations requiring pacing are clear and have not changed over the years (e.g. high-degree atrioventricular block and sinus node dysfunction), many others have evolved and have been the subject of extensive research (e.g. pacing following transcatheter aortic valve implantation and cardiac resynchronisation therapy for heart failure). Increasing attention has also developed in other areas, such as how to avoid complications of cardiac pacing, pacing in patients after cardiac surgery and leadless pacing. [3]

Furthermore, when urgent pacing is required, it is also essential that the intensive care physician is skilled in aspects of temporary pacing, including lead insertion and testing.

The use of implantable cardioverter-defibrillators (ICD) in patients at high risk of life-threatening ventricular arrhythmias, has become more widespread, and it will also be addressed in this chapter.

Types of Pacing: General Description

Cardiac pacemakers generally consist of two components: a pulse generator, which provides the electrical impulse for myocardial stimulation; and one or more electrodes (commonly referred to as leads), which deliver the electrical impulse from the pulse generator to the myocardium (Fig. 32.1).



The two diagrams depict a heart with a pacemaker device in two distinct views labelled A and B. In the view labelled A, the leads extend from a pacemaker device positioned above the heart. These leads connect to pace electrodes located inside the heart. In the view labelled B, a leadless pacemaker is situated within the heart. The arrows point to the respective components.

FIG. 32.1 Permanent pacemaker (A) and leadless pacemaker (B). (From Sharma D, Kanaujia BK, Kaim V, et al. Design and implementation of compact dual-band conformal antenna for leadless cardiac pacemaker system. *Sci Rep* . 2022;12:3165. doi: 10.1038/s41598-022-06904-2)

Endocardial Pacing

Pacing leads are passed via a vein to the endocardial surface of the right atrium, the right ventricle (RV) or both chambers. In patients with heart failure, an additional lead is placed in the coronary sinus. They have the ability to sense cardiac activity and provide therapeutic cardiac stimulation.

Balloon-flotation pacing catheters for temporary pacing are less stable and are generally reserved for emergency pacing purposes.

Epicardial Pacing

An epicardial pacemaker system is needed in some clinical scenarios: patients with congenital anomalies and no venous access to the heart, recurrent device infections, and, most commonly, in conjunction with open cardiac surgery. Epicardial leads are implanted using thoracotomy or thoracoscopy, and robotic techniques.[4]

Leadless Pacing

Miniaturised, intracardiac leadless pacemakers have been introduced. These devices are inserted percutaneously through the femoral vein and implanted directly in the RV wall. They provide effective single-chamber pacing therapy[5] (Fig. 32.1).

Cardiac Resynchronisation Therapy (CRT)

CRT delivers biventricular pacing to correct electromechanical dyssynchrony to increase cardiac output.[6] CRT has shown a significant morbidity and mortality benefit in certain groups of patients with reduced left ventricular ejection fraction.[7]

Transcutaneous External Pacing

Transcutaneous pacing can be instigated rapidly in an emergency whilst waiting for a more permanent strategy (e.g. transvenous pacing).[8] Patches are applied anterolaterally or anteroposteriorly over the heart. Conscious patients will require analgesia or sedation to avoid experiencing significant pain.[9] This modality should only be used in emergency settings or when no other option is available, and under close haemodynamic monitoring.[10]

To commence emergency transcutaneous pacing, the pacemaker is set to demand with a pacing rate greater than 30 bpm above the patient's intrinsic rhythm. The current is set to 70 mA and increased until the pacing rate is captured on the monitor. If capture is insufficient at a current of 120–130 mA the electrodes should be re-sited and the above procedure repeated. Once pacing capture is achieved and stable, the current is reduced until capture is lost and increased until regained; this is the pacing threshold. The current should be set and maintained at 5–10 mA above the threshold.

Pacing nomenclature

A three-letter code describing the basic function of the various pacing systems was first proposed in 1974. This was subsequently updated by a committee from the North American Society of Pacing and Electrophysiology and the British Pacing and Electrophysiology Group. The code, which has five positions, is designated the North American and British Group (NBG) pacemaker code and is used to identify modes of pacing.[11]

- *Position I:* refers to the chamber(s) paced: A = atrium, V = ventricle, and D = dual chamber (i.e. both A and V).
- *Position II:* refers to the chamber(s) sensed: A, V, and D. An additional option 'O' indicates an absence of sensing. In this mode, a device will pace automatically at a specified rate, ignoring any intrinsic rhythm.
- *Position III:* refers to how the pacemaker responds to a sensed event. This may be:
  - I (inhibition) – a pacemaker's discharge is inhibited (switched off) by a sensed signal, for example VVI, where ventricular pacing is inhibited by spontaneous ventricular activity.
  - T (triggered) – a pacemaker's discharge is triggered by a sensed signal.

  - D (dual) – both T and I responses can occur. This designation is restricted to dual-chamber systems. An event sensed in the atrium inhibits the atrial output but triggers a ventricular output. There is a programmable delay (the atrioventricular (AV) interval) between the sensed atrial depolarisation and the triggered ventricular pacing, which mimics the normal PR interval. If a spontaneous ventricular depolarisation is sensed during the programmed delay, it will inhibit ventricular pacing.
  - O – no response to sensed input; it is most commonly used in conjunction with an 'O' in the second position.
- *Position IV:* refers to rate-responsive pacing and is only relevant to permanent systems. An *R* indicates that the pacemaker has rate modulation, meaning that the pacemaker system strives to produce an appropriate compensatory heart rate during emotional or physical activity by sensing body motion/acceleration, minute ventilation, intracardiac impedance or other surrogates of physical and mental stress. [12] They are indicated in cases of chronotropic incompetence.

Minute ventilation sensors may inappropriately accelerate the pacing rate in mechanically ventilated patients requiring a large minute volume. Changing the 'upper rate' limit of the pacemaker or switching off the rate-responsive function will solve the problem.

Dual-sensing rate-responsive pacing (e.g. accelerometer and minute ventilation) may be used in selected patients. [13]

- *Position V:* rarely ever utilised, indicates whether multisite pacing is present. O = no multisite pacing; A = multisite pacing in the atrium or atria; V = multisite pacing in the ventricle or ventricles; D = any combination of atria and ventricles. For example the code for a patient with dual-chamber rate-responsive pacing (DDDR) and biventricular pacing is DDDRV.

Pacing modes

In selecting the ideal pacing mode, the patient’s overall physical condition, associated medical problems, exercise capacity, left ventricular function and chronotropic response to exercise must be considered along with the underlying rhythm disturbance.

The three-position code is adequate to describe emergency temporary pacing and most forms of permanent pacing in the intensive care unit (ICU).

Single-Chamber Pacing

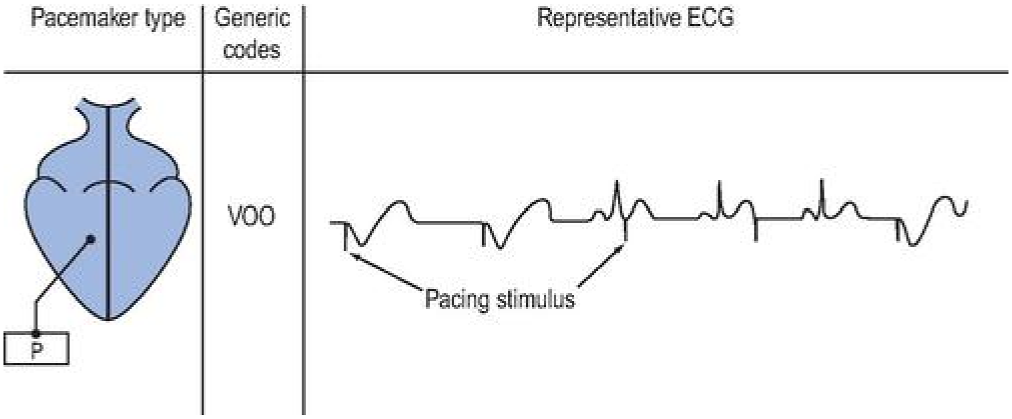
Early pacemakers were designed to sense and pace in a single chamber.

1. *AOO and VOO pacing (asynchronous):* In this mode, there is no ability to sense cardiac activity (Fig. 32.2). Asynchronous pacing modes are rarely used long-term. However, it may be temporarily necessary for patients exposed to external sources of noise (e.g. surgical diathermy or magnetic resonance imaging (MRI) scanning), especially if the patient is pacemaker dependent.

    Alternatively, a magnet placed over the pacemaker will deactivate its ability to sense and, whilst left in place, will result in asynchronous pacing.

    During VOO pacing, there is a possibility that a paced impulse will occur during a native T wave (or the vulnerable period), causing malignant ventricular arrhythmias (Fig. 32.3).
2. *AAI pacing (atrial demand):* This is indicated in patients with sinus node dysfunction (SND) and intact AV conduction. It is reserved for patients in whom the risk of developing AV block is thought to be low since it would not protect patients from ventricular bradyarrhythmias. Due to this limitation, permanent AAI pacemakers are infrequently used.
3. *VVI pacing (ventricular demand) (Fig. 32.4):* This remains the most commonly used pacing mode and the mode of choice in life-threatening bradyarrhythmias. Spontaneous cardiac rhythm is sensed, and a minimum ventricular rate is programmed to prevent symptoms. VVI pacing cannot maintain AV synchrony, and this can

result in pacemaker syndrome (*Fig. 32.5E*). Also, the lack of AV synchrony may reduce cardiac output by up to 25%. Hence, it is primarily indicated in patients with chronic atrial fibrillation.



The diagram consists of two main sections. On the left, an illustration of a heart contains a pacemaker marked with the letter P. Above the illustration, a table spans the width of the diagram with two headers. The left header reads Pacemaker type and right header reads Generic codes and lists V O O. The adjacent header reads Representative Electrocardiogram and presents a trace with a wavy line pattern, labelled Pacing stimulus.

FIG. 32.2 Asynchronous, fixed-rate ventricular pacing – VOO. *ECG* , Electrocardiography; *P* , pacemaker.

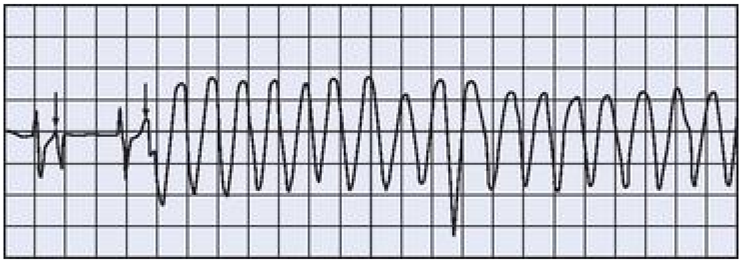


FIG. 32.3 Non-sensing of QRS (see first two beats). Pacing spikes *(arrows)* fall on the T wave with subsequent pacemaker-induced ventricular tachycardia.

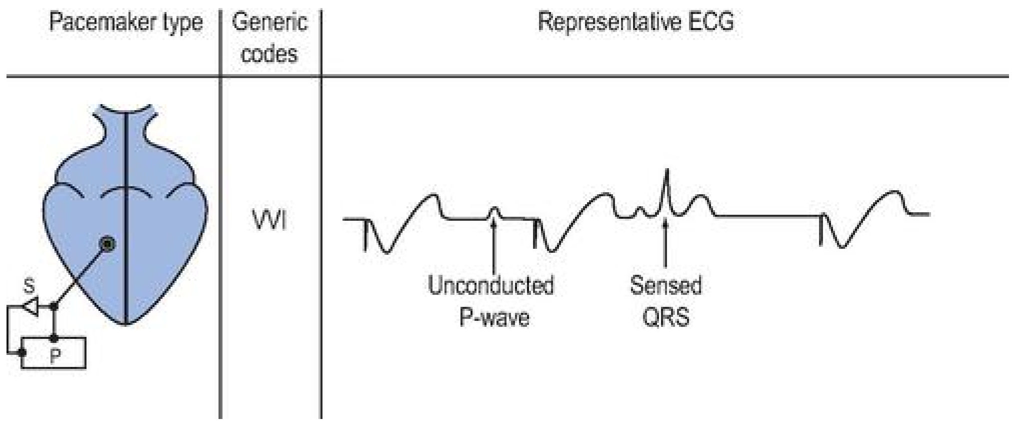

The diagram consists of two main sections. On the left, an illustration heart contains a pacemaker marked with the letter P and a sense electrode marked with the letter S. A line connects the pacemaker to the sense electrode within the heart. Above the illustration, a table spans the width of the diagram with two headers. The left header reads Pacemaker type and the right header reads Generic codes and lists V V I below it. The adjacent header reads Representative Electrocardiogram and presents a trace with a wavy line pattern. The trace includes two labels. The first label reads Unconducted P wave and points to a small upward wave. The second label reads Sensed Q R S and points to a larger wave pattern that follows.

The series of five electrocardiogram traces is arranged vertically from top to bottom. The traces are labelled A, B, C, D, and E in sequence. Each trace has a label above it that reads Electrocardiogram Lead two, followed by specific measurements. For trace A, the measurement reads zero point one millivolts per millimetre. For trace B, the measurement reads zero point one millivolts per millimetre. For trace C, the measurement reads zero point two millivolts per millimetre. For trace D, the measurement reads zero point one millivolts per millimetre. For trace E, the measurement reads zero point one millivolts per millimetre. In trace E, two arrows point specific points on the trace.

FIG. 32.5 ECG patterns of dual-chamber devices (A) Complete inhibition (sinus rhythm is present with intact atrioventricular conduction). (B) Atrial pacing with intact atrioventricular conduction. (C) Ventricular tracking of a sensed atrial rhythm (P-synchronous ventricular pacing). (D) Atrioventricular sequential pacing. (E) Single-chamber right ventricular pacing. Arrows point to smaller deflections occurring at a slower rate, which might represent P waves or baseline artefact. *AP* , paced atrial rhythm; *AS* , sensed intrinsic atrial rhythm; *VP* , paced ventricular rhythm; *VS* , sensed intrinsic ventricular rhythm. (Reproduced with permission from Trohman RG, Kim MH, Ponski SL. Cardiac pacing: the state of the art. *Lancet* . 2004;364(9446):1702, Figure 1 .)

Dual-Chamber Pacing (Fig. 32.5)

The dual-chamber pacing system provides physiologic pacing, with sensing and pacing capabilities in both the atrium and the ventricle.

1. *DDD pacing* : the ideal patient for this pacing mode is one with combined sinus nodal and AV nodal dysfunction. The use of DDD

pacing with an algorithm that will minimise ventricular pacing is strongly recommended.

The response to DDD pacing depends on the underlying cardiac rhythm:

- Normal sinus rhythm with normal AV conduction: inhibition of both atrial and ventricular pacing (Fig. 32.5A).
- Sinus bradycardia with intact AV conduction – atrial pacing with a native QRS (Fig. 32.5B).
- Normal sinus rhythm with high-degree AV block – atrial sensing and ventricular pacing (Fig. 32.5C).
- Sinus bradycardia with AV block – AV sequential pacing (Fig. 32.5D).

2. *DDI pacing (AV sequential, non–P-wave synchronous):* In this mode, sensing occurs in both atrium and ventricle but sensed atrial events do not trigger ventricular pacing. There are few advantages, if any, of DDI pacing. In the past, this mode was helpful for the patient with atrial tachyarrhythmias. Since DDI does not 'track,' this mode would alleviate the concern of fast ventricular rates in response to an atrial tachyarrhythmia. However, this has become much less important since all dual-chamber devices now have mode-switching capability.

Permanent cardiac pacing therapy

Indications

Permanent pacemaker implantation is most commonly indicated for SND or high-grade/symptomatic AV block. Although some indications for permanent pacing are relatively certain or unambiguous, others require considerable expertise and judgement.

Guidelines for the implantation of cardiac pacemakers have been published by a joint American task force. [14] Similar guidelines have been established by the European Society of Cardiology. [3] Below we present the

class I indications , when *benefit clearly outweighs the risks* and so, treatment should be performed:

1. **In sinus node dysfunction:**
    - when symptoms can clearly be attributed to bradyarrhythmias
    - with symptomatic bradycardia-tachycardia form of SND to correct bradyarrhythmias and enable pharmacological treatment, unless ablation of the tachyarrhythmia is preferred
2. **In atrioventricular block:**
    - patients in sinus rhythm (SR) with permanent or paroxysmal third- or second-degree type 2, infranodal 2:1, or high-degree AV block, irrespective of symptoms
    - patients with atrial arrhythmia (mainly atrial fibrillation [AF]) and permanent or paroxysmal third- or high-degree AV block, irrespective of symptoms
3. **For conduction disorders without AV block:**
    - alternating bundle branch block, irrespective of symptoms
4. **For reflex syncope**
    - in patients aged >40 years, with severe, unpredictable, recurrent syncope who have:
        - spontaneous documented symptomatic asystolic pause(s) >3 seconds or asymptomatic pause(s) >6 seconds due to sinus arrest or AV block;
        - cardioinhibitory carotid sinus syndrome; or
        - asystolic syncope during tilt testing

Indications for pacing in specific conditions

1. **Heart failure: cardiac resynchronisation therapy**

CRT improves cardiac function, symptoms, and well-being, and reduces morbidity and mortality in an appropriately selected group of heart failure (HF) patients. [15]

Class I indications for CRT currently are:

- Symptomatic patients with HF in SR with left ventricle ejection fraction (LVEF) ≤35%, QRS duration ≥150 ms, and left bundle branch block QRS morphology despite optimal medical therapy, to improve symptoms and reduce morbidity and mortality. [16]
- Symptomatic patients with AF and an uncontrolled heart rate who are candidates for AV junction ablation (irrespective of QRS duration), if LVEF <40%. [17]
- CRT rather than RV pacing is recommended for patients with LVEF <40% regardless of NYHA class who have an indication for ventricular pacing and high-degree AV block to reduce morbidity. This includes patients with AF. [18]

2. **Acute myocardial infarction**

In patients with acute myocardial infarction (MI), significant bradyarrhythmia may occur due to autonomic influences or damage of the conduction system by ischaemia and/or reperfusion.

Implantation of a permanent pacemaker is indicated with the same recommendations as in a general population when AV block does not resolve within a waiting period of at least 5 days after MI (Class I). [3]

3. **After cardiac surgery and heart transplantation**

AV block may occur in 1%–4% of cases after cardiac surgery and in ~8% after repeat valve surgery. [19], [20]

In patients that develop high-degree or complete AV block after cardiac surgery, a period of clinical observation of at least 5 days is indicated to assess whether the rhythm disturbance is transient and resolves. However, in the case of a complete AV block with low or no escape rhythm when resolution is unlikely, this observation period can be shortened (Class I). [21] Predictors of long-term pacemaker dependency are complete AV block as the indication, bypass time longer than 105–120 minutes, pre-operative history of syncope and body mass index ≥28.5 kg/m^2. [22]

After heart transplantation, SND is common and leads to permanent pacemaker implantation in 8% of patients. [23] Cardiac pacing should be considered for chronotropic incompetence persisting for >6 weeks to improve quality of life. [24]

4. **After transcatheter aortic valve implantation (TAVI)**

Rates of permanent pacemaker implantation after TAVI range between 3.4% and 25.9%. [25], [26]

Permanent pacing is recommended in patients with complete or high-degree AV block that persists for 24–48 hours after TAVI [27] and, in patients with new-onset alternating bundle branch block [28] (Class I).

5. **In hypertrophic cardiomyopathy (HCM)**

In patients with symptoms caused by LV outflow tract obstruction treatment options include drugs, surgery, septal alcohol ablation, and AV sequential pacing with a short AV delay. However, the evidence to support this is weak (Class IIb) [29] and shared decision-making should be employed when considering the treatment of choice for patients with obstructive HCM.

6. **In rare diseases**

Neuromuscular diseases, mitochondrial cytopathies, and infiltrative, metabolic and inflammatory diseases might require permanent pacing. [3] The indications for those are beyond the scope of this chapter.

Temporary pacing

Temporary pacing can provide electronic cardiac stimulation in patients with acute life-threatening bradycardia or can be placed prophylactically when the need for pacing is anticipated (e.g. after cardiac surgery). [30]

Modalities for emergency temporary pacing include transvenous, epicardial and transcutaneous approaches.

Indications for Temporary Transvenous Pacing

- It is recommended in cases of haemodynamic-compromising bradyarrhythmia refractory to intravenous chronotropic drugs (Class I). [30]
- Should be considered when immediate pacing is indicated and pacing indications are expected to be reversible (e.g. myocardial ischaemia, myocarditis, electrolyte disturbance and toxic exposure) (Class IIa). [31]

Technique of Temporary Transvenous Pacing

Vascular access

The Seldinger technique is used to access a central vein with a 5- or 6-French sheath. There are no good data that support either a jugular or axillar/subclavian access. A jugular access should be preferred if implantation of a permanent ipsilateral device is planned. In selected cases where fast and efficient pacing is needed, a femoral access may be used. Owing to the instability of passive leads placed through the femoral vein and immobilisation of the patient, the duration of this approach should be as short as possible.

Placement of ventricular lead

The transvenous approach often requires fluoroscopic guidance, although echo-guided placement is also feasible. [32] Balloon-tipped floating catheters are easier to insert, more stable, and safer than semi-rigid catheters. [33]

Manipulation of the lead is achieved by clockwise and counterclockwise torque in combination with simultaneous advancement and retraction of the lead. The final position should be close to the apex of the RV (Fig. 32.6). This position offers the greatest stability, but the true apex should be avoided as it is thin, and the risk of perforation is higher.

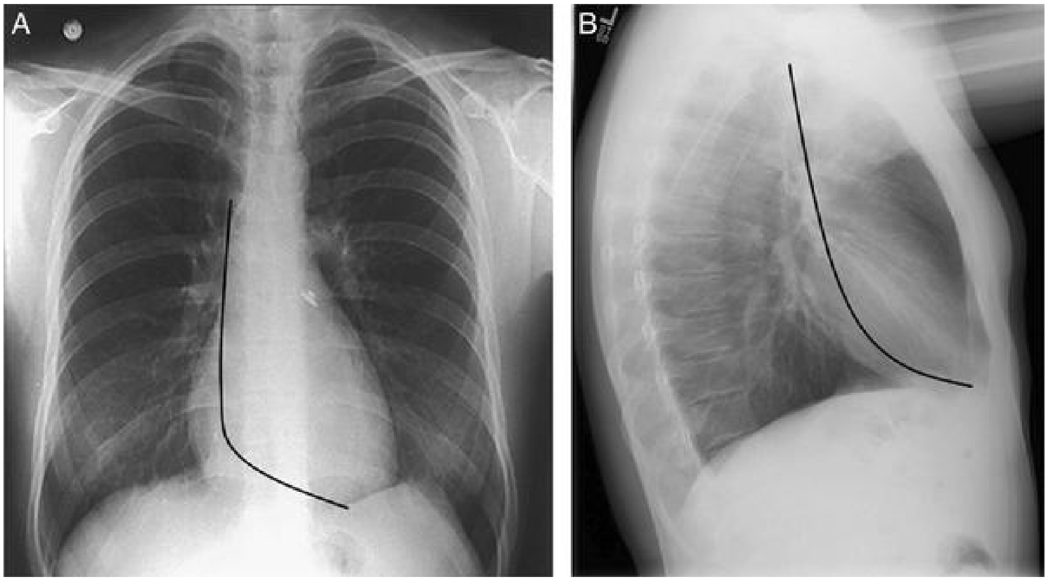

FIG. 32.6 Posteroanterior (A) and lateral (B) chest radiographs, with a line that diagrams the expected course of a right ventricular apical pacemaker lead. (Reproduced with permission from Belvin D, Hirschl D, Jain VR, et al. Chest radiographs are valuable in demonstrating clinically significant pacemaker complications that require reoperation. *Can Assoc Radiol J.* 2011;62(4):290, Figure 1 . Copyright Elsevier.)

Once in a satisfactory position, the lead should be tested electrically for sensing, pacing and diaphragmatic capture (see below). It should be sutured to the skin at two different sites: one where it exits the skin, and a second to a loop formed with the lead. A chest X-ray should be obtained to exclude pneumothorax and to confirm satisfactory positioning.

Complications of Temporary Transvenous Pacing

Several studies from the UK report complications in a third to a half of cases. [34-36] Thus, temporary transvenous pacing is best avoided where possible; rather, insertion of a permanent system at the earliest opportunity is best and in many centres, this now happens out of ‘normal’ working hours.

- *Procedure-related complications* : cardiac perforation with pericardial effusion and tamponade, bleeding, pneumothorax, haemothorax, malfunction (e.g. undersensing, oversensing and failure to capture), arrhythmias and accidental lead displacement.

- *Immobilisation-related complications* : infection, delirium, and thrombotic events.

In addition, previous temporary pacing is associated with an increased risk of permanent pacemaker infection.[37]

Trying to reduce the incidence of complications associated with temporary transvenous pacing, in patients that will need long-term temporary transvenous pacing (e.g. due to concomitant infection), an active-fixation lead inserted through the skin and connected to an external pacemaker should be considered (the so-called ‘temporary-permanent system’ or ‘externalised pacemaker’)[38] (Fig. 32.7). After a short period of observation, the patient can be mobile and lead displacement and threshold rise are rare, meaning the need for the lead repositioning is also rare. The device can be reprogrammed just like any other permanent pacemaker, and the percentage of time that the patient is pacing, or detection of intermittent arrhythmias, can be recorded so where appropriate, a decision to permanently pace or provide other treatment can be made. If the patient does not need a permanent system, removal of the temporary-permanent system is straightforward.

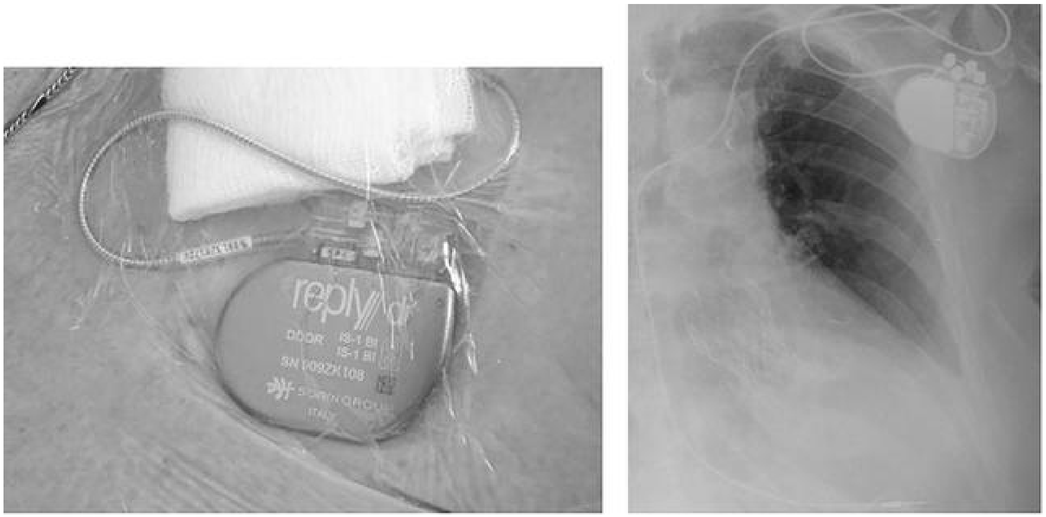

FIG. 32.7 Active-fixation lead is connected to a reusable generator secured to the skin with a large occlusive dressing to maintain sterility (A). Chest radiography showing the position of the pacing lead. The active-fixation screw mechanism and the CoreValve are visible (B). (Reproduced with permission from Cuisset T, Quilici J. Subclavicular screwed wire transient pacing to increase safety of transcatheter aortic valve implantation with the CoreValve system. *J Cardiol Cases* . 2011;3(3):e168, Figures 1 and 2 .)

Testing the Pacing Leads

Modern external pacing boxes are available (Fig. 32.8) that will pace in all modes. These units are small, easy to use and can fit into a small pouch suitable for mobile patients. Furthermore, they can perform checks of pacing threshold and sensing.

1. **Pacing threshold:** It is the minimum energy required to be delivered by the pacing system to achieve electrical capture.
    - Set the pacemaker rate at least 10 beats per minute (bpm) faster than the intrinsic heart rate, or at 60 bpm if the patient has a profound bradycardia.
    - Set the pacing output at 5 V.
    - Confirm ventricular capture (pacing spike immediately followed by a broad QRS at the same rate as that set on the box).

- Decrease the output slowly until capture is lost (pacing spike no longer followed by a broad QRS). This is the pacing threshold and ideally should be less than 1 V.
- Set the output to three times the pacing threshold to allow sufficient safety margin, or at least 3 V.

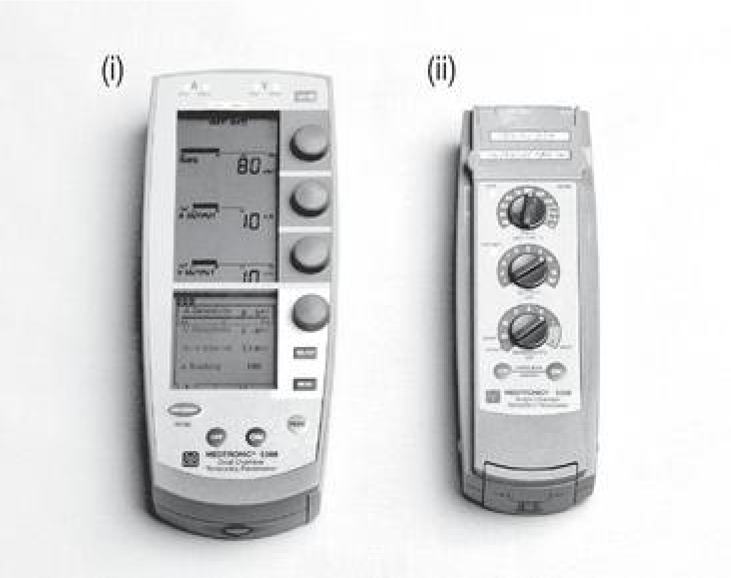

FIG. 32.8 Temporary pacing systems. Medtronic, Inc. (i) Model 5388 (dual-chamber); (ii) model 5348 (single-chamber).

In those with no underlying rhythm or profound bradycardia, loss of capture will lead to asystole – in which case the output should be rapidly increased until capture returns.

2. Pacing sensitivity/sensing

Sensitivity, or sensing, refers to the amplitude of the sensed electrograms. Large electrograms are easy to sense and small ones are not and undersensing may occur.

- Set the pacemaker rate at least 10 bpm slower than the intrinsic heart rate (not possible if extremely slow underlying rhythm or asystole).

- Set the pacing sensitivity at 1mV and the pacing output to the lowest to avoid pacing on the T wave.
- Confirm ventricular sensing (flashing light on the pacing box and no spikes should be seen).
- Increase the sensitivity number (>1 mV) until you see a pacing spike/failure of sensing. This represents the sensitivity threshold of the sensed electrograms.
- Set the sensitivity to a half to a third of the sensitivity threshold, to allow continuous sensing of all intrinsic signals (e.g. if it senses at 8 mV, set it at 4 mV or less).
- Do not forget to increase the pacing output.

Pacemaker Programming

Multiple parameters can be programmed on temporary and permanent pacing systems. All pacing practitioners, and this includes physicians who implant temporary systems, should be familiar with programming the mode, rate, pacing output and sensitivity of a pacing system. In addition, they should also be able to diagnose and troubleshoot basic pacing problems like undersensing and oversensing. If dual-chamber pacing systems are used, programming the AV delay should be performed to optimise cardiac output and cardiac function (using echocardiographic guidance). Programming permanent pacing systems is more complicated than for temporary systems and should be performed only by individuals qualified to do so.

Troubleshooting

The incidence of pacing system malfunction is difficult to determine due to inconsistent definitions and the lack of any comprehensive reporting mechanism or registry. [39] The malfunctions discussed here will be limited to those that are manifest on an electrocardiogram rhythm strip.

1. **Pacing stimuli present with loss of capture**

Loss of capture is the failure of the pacemaker stimulus to produce electrical activation of the heart and a subsequent cardiac contraction. The diagnosis of loss of capture is based upon the presence of a pacing stimulus, without a subsequent P wave or QRS complex (Fig. 32.9). The result can be asystole or bradycardia, depending on the patient's underlying rhythm.

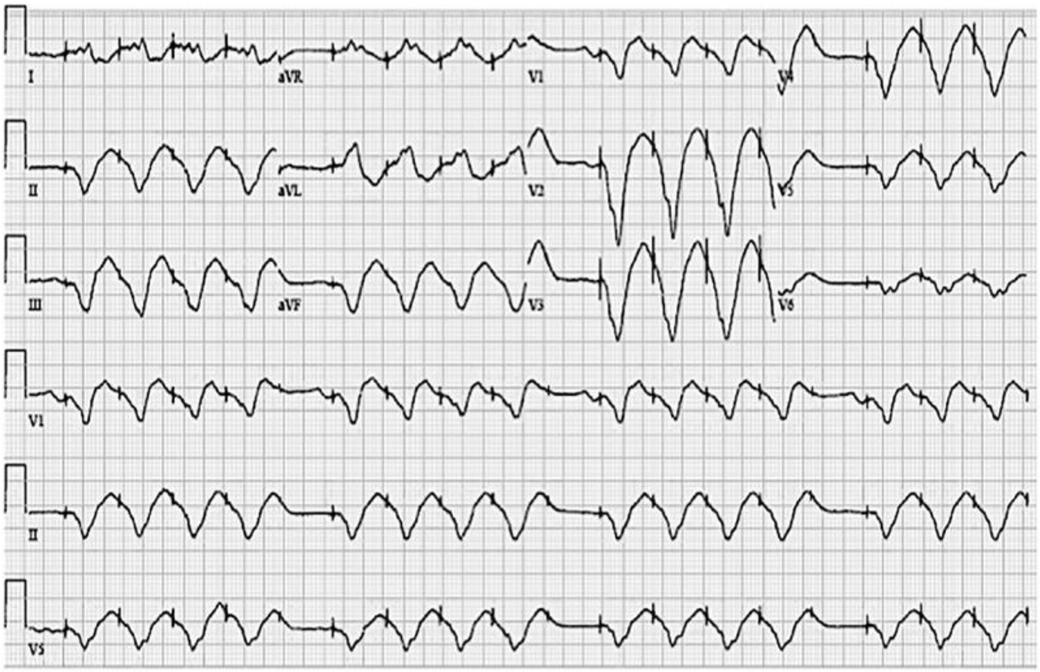

FIG. 32.9 Baseline paced electrocardiogram. Electrocardiogram shows atrial sensed ventricular paced rhythm at 115 beats per minute with group beating due to intermittent failure to capture. (Reproduced with permission from Padala SK, Sharma PS, Ellenbogen KA, Koneru JN. Intermittent failure to capture: what is the mechanism? *HeartRhythm Case Rep* . 2016;2(2):180, Figure 1A .)

Causes: increase in pacing threshold above programmed value; lead dislodgement or malposition; inflammation and fibrosis at the electrode/myocardial interface raising the threshold for stimulation; lead failure; battery depletion.

2. **Pacing stimulus present with failure to sense**

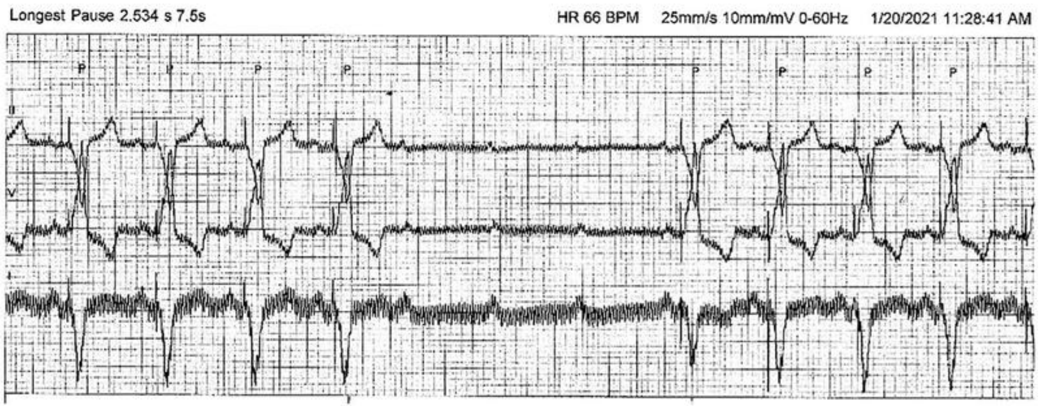
The second major functional capability of a pacemaker is the ability to sense or recognise intrinsic cardiac depolarisations.

Undersensing is the failure to sense an event. This will cause inappropriate delivery of a pacing stimulus. If this occurs on or near a T wave, this can lead to ventricular fibrillation (VF) (Fig. 32.3).

Causes: pacemaker programmed to a value insufficient to sense intrinsic activity; change in native signal (e.g. as a consequence of MI); lead failure; magnet application inducing asynchronous function.

3. Pacing stimuli absent

The absence of pacing stimuli is appropriate when there is an intact native rhythm which inhibits pacemaker output. However, one should not observe an absence of pacing stimuli with pauses in the rhythm that are longer than the programmed base rate of the pacemaker (Fig. 32.10).



Longest Pause 2.534 s 7.5s
HR 66 BPM 25mm/s 10mm/mV 0-60Hz 1/20/2021 11:28:41 AM
P

P
P
P
P
P
P

The electrocardiogram trace spans an entire width. At the top left, a label reads Longest Pause two point three four seconds. Next to it, another label reads Heart Rate sixty Beats Per Minute. Further to the right, additional text reads twenty five millimetres per second and ten millimetres per millivolt followed by D four H. A date and time stamp is on the far right. The trace below consists of a series of peaks and troughs that repeat across the grid.

FIG. 32.10 ECG shows intermittent loss of ventricular pacing with a prolonged pause (oversensing event). (Reproduced with permission from Pai PG, Hegde NN. Troubleshooting a pacemaker output failure: a case report. *J Electrocardiol* . 2021;66:149, Figure 2 .)

Causes: oversensing; lead fracture.

Oversensing of an inappropriate signal can be corrected by reducing the pacemaker sensitivity (i.e. programming the pacemaker to a higher sensitivity number). However, reducing the sensitivity predisposes to episodes of undersensing and careful programming is needed.

4. **Electromagnetic interference**

Any signal sensed by a pacemaker will lead to pacing being inhibited or triggered. These signals will include noise or electrical artefact sensed by a pacing system. Noise can be intrinsic (from within the patient) or extrinsic (from outside the patient). Sources of intrinsic noise include lead fracture, fluid in the generator header and diaphragmatic and skeletal myopotentials. Extrinsic noise includes electromagnetic interference (EMI) (e.g. surgical diathermy, cardioversion or defibrillation, MRI).

- **Peri-operative management:** advisory documents to help manage patients in the peri-operative period have been issued. [40] The most common source of EMI is electrocautery, although it is rare with bipolar diathermy. Other sources of EMI include radiofrequency procedures, nerve stimulators, and other electronic devices.

  The peri-operative strategy should be tailored based on the individual needs. Most procedures will not require any intervention. [41] In pacemaker-dependent patients, a magnet should be applied during delivery of diathermy pulses, or, if EMI is likely to occur the device should be programmed to an asynchronous mode. Post-operative interrogation of the device is recommended if malfunction is suspected or if the device has been exposed to strong EMI.
- **External cardioversion/defibrillation:** the pads should be placed in the anterior-posterior position and as far from the pulse generator as possible, without compromising the efficacy of the procedure. The device should be checked before and afterwards. With appropriate positioning the procedure can be safely performed with minimal risk to the implanted device. [42]
- **MRI:** MRI is a frequent requirement in patients with implanted pacemakers. It may cause adverse effects such as inappropriate device function due to device reset or sensing problems, induction of currents resulting in myocardial capture, heating at the lead tip with changes in sensing or capture thresholds, or lead perforation. All aspects of MRI imaging are detailed in a professional society consensus document [43] and go beyond the scope of this chapter. Evaluation must be made on a case-by-case basis by balancing the advantages of MRI with the potential risks and availability of

alternative imaging methods [44] (e.g. in patients with abandoned transvenous leads if no alternative imaging modality is available, MRI may be considered – Class IIb). [45]

Cardiac pacing in tachyarrhythmias

Pacing for the prevention of tachyarrhythmias

- **Post-cardiac surgery:** overdrive pacing, which means pacing the heart at a higher rate than the native heart rate, has been used after cardiac surgery to prevent AF and atrial flutter, although beta-blockers are usually the treatment of choice. [46]
- **Ventricular tachyarrhythmias:** some ventricular tachycardias can be prevented by rapid pacing. An example is Torsades de Pointes. Atrial or ventricular pacing at rates between 90 and 110 bpm, can prevent initiation of Torsades de Pointes by shortening the QT interval and by preventing premature ventricular ectopics that might trigger the tachycardia.

Overdrive pacing for the treatment of tachyarrhythmias

Although pacemakers are not usually inserted for the treatment of atrial arrhythmias, overdrive pacing can be attempted to treat AV junctional tachycardia, re-entrant supraventricular tachycardia and atrial flutter.

It can also be used for the treatment of ventricular tachycardia (VT). The ventricle is paced at a rate starting at about 120% of the VT rate for 8–10 beats (Fig. 32.11). If this fails (Fig. 32.12), increasing the pacing rate and/or the number of paced beats in the train should be tried cautiously. Slow VTs are very stable and often require very long-pacing trains. Potential complications include accelerating the VT rate, which can precipitate VF. Trained personnel, a defibrillator and resuscitation facilities must be available to perform this safely.

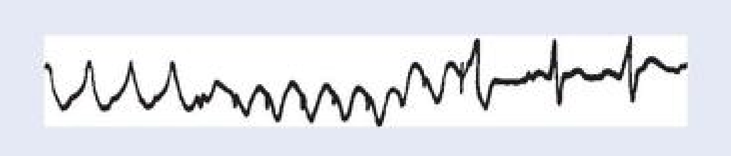

FIG. 32.11 Wide-complex tachycardia. Ventricular burst pacing with ventricular capture results in normal sinus rhythm on cessation of pacing.

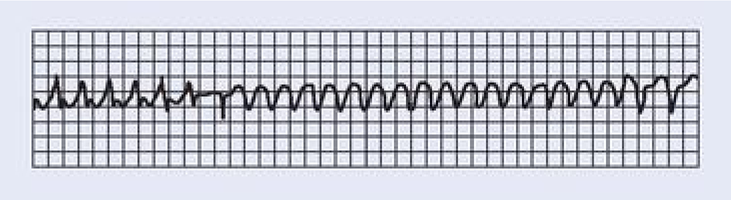

FIG. 32.12 Wide-complex tachycardia is followed by ventricular burst pacing. When pacing is discontinued, a wide-complex tachycardia of opposite polarity is precipitated.

Overdrive pacing has advantages over DC cardioversion (Box 32.1) and drug therapy (Box 32.2), but is of no value in sinus tachycardia, AF and VF.

Box 32.1

Overdrive pacing versus cardioversion

Pacing may assist in rhythm diagnosis
Pacing may be used (cautiously) in digitalis intoxication
Pacing does not require a general anaesthetic
Pacing avoids complications of DC shock, especially myocardial depression

Pacing is immediately available if bradycardia or asystole occurs after electrical reversion

Box 32.2

Overdrive pacing versus drug therapy

Pacing may aid in rhythm diagnosis
Pacing avoids drug-induced cardiac depression and other drug side effects
Pacing can be used when drug therapy has failed
Termination of the tachycardia with pacing is often immediate
Standby pacing is immediately available

Cardiac Pacing and Haemodynamics

There is extensive literature regarding the use of echocardiography in CRT, [47] however, the potential impact of pacing optimisation in critically ill patients has been barely explored. [48]

One well-validated parameter, known to potentially limit cardiac output is the total isovolumic time (t-IVT). [49] This measure of global left ventricular electromechanical dyssynchrony represents the total amount of time the heart is neither filling nor ejecting. A value of greater than 14 seconds/min is considered LV systolic electromechanical inefficiency. [49] An abnormally prolonged t-IVT is not uncommon in the critically ill, being present in up to 22% of cardiac and respiratory patients. [50]

The use of standardised echocardiography-guided pacing optimisation protocols [48] might lead to increase in cardiac index by reducing the t-IVT, by finding the optimal heart rate and AV delay.

Implantable cardioverter-defibrillators

ICD use is becoming more widespread within cardiology and are therefore likely to be seen more often in patients admitted to ICU. They are implanted in patients at high risk of life-threatening ventricular arrhythmias. [51] ICD implantation is generally considered the first-line treatment option for the secondary prevention of sudden cardiac death (SCD) and for primary prevention in certain populations at high risk of SCD due to VT/VF.

The ICD system is comprised of pacing/sensing electrodes, defibrillation electrodes and a pulse generator. [52] In contemporary transvenous ICDs, both the pace/sense electrodes and the defibrillation electrodes are located on a single ventricular lead. They can be single, dual or biventricular systems.

ICD functions

- **ECG monitoring and storage:** recording and display of stored electrograms from tachyarrhythmia events; telemetry capabilities; and remote monitoring capabilities.
- **Anti-tachycardia pacing:** refers to the delivery of short bursts (e.g. eight beats) of rapid ventricular pacing to terminate VT. Although a variety of algorithms exist, anti-tachycardia pacing is usually programmed to be delivered at a rate that is slightly faster than the rate of the detected tachycardia.
- **Cardioversion/defibrillation:** synchronised cardioversion can often terminate VT with relatively low energy (e.g. 10 joules or less). ICDs can be programmed to deliver unsynchronised shocks (defibrillation) for very rapid ventricular arrhythmias (e.g. heart rate greater than 200 beats/min).
- **Bradycardia pacing:** all contemporary transvenous ICDs are capable of pacing.

Complications

Most of the considerations made for pacemaker troubleshooting are equally valid in patients with ICDs. Other important occurrences in these patients include the delivery of inappropriate ICD shocks, ICD storms or ineffective

ICD therapies. Specialist input is invariably required in troubleshooting these devices.

Magnet application over an ICD will prevent the device from sensing and delivering any therapies, which is useful in patients with inappropriate ICD shocks or ICD storms.

Acute heart failure and pulmonary hypertension

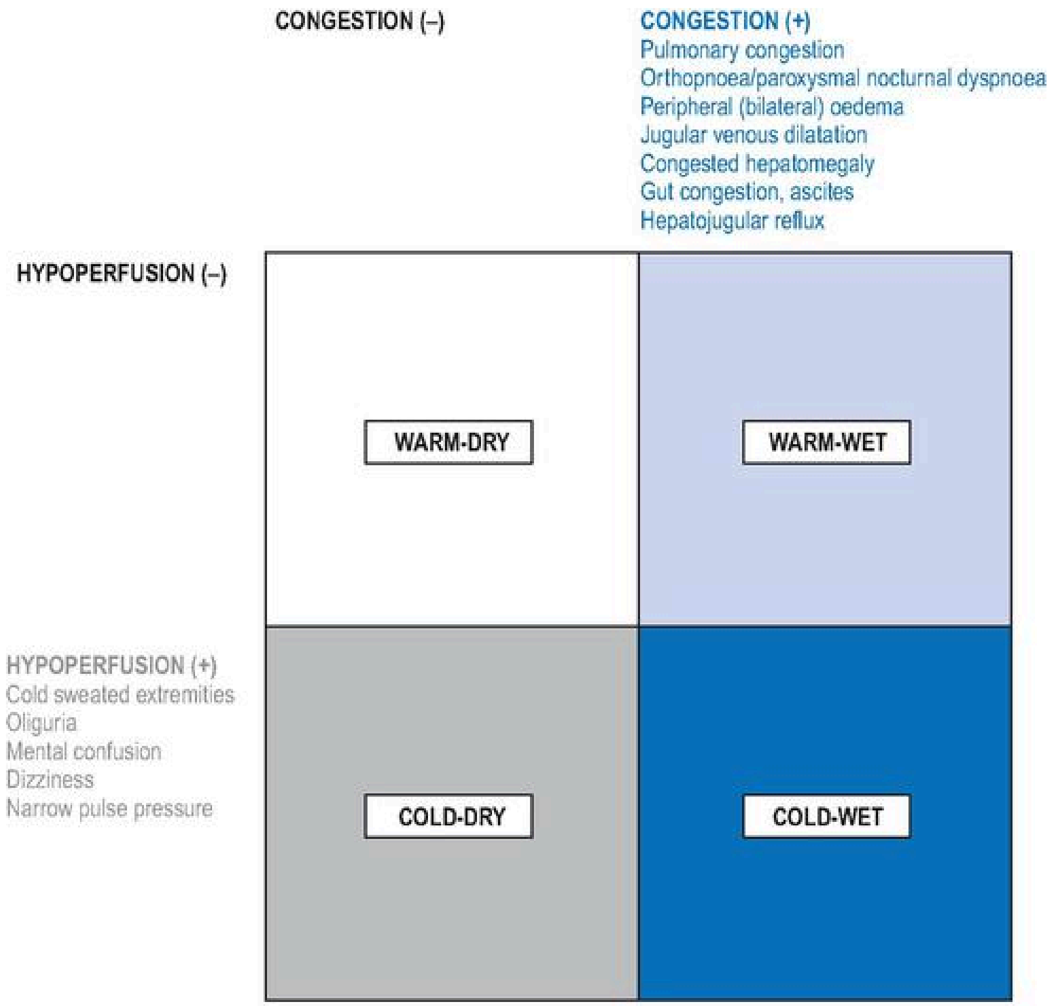
Daniel Taylor and Nicholas Ioannou

Acute Heart Failure

Heart failure is a highly prevalent condition affecting 1%–3% of the population worldwide [1] accounting for 2% of all healthcare expenditure in developed economies. [2] Most patients with heart failure have underlying coronary artery disease, hypertension, pre-existing cardiomyopathy or valvular disease. Improvements in the detection and treatment of patients with chronic heart failure (CHF) and those presenting with acute coronary syndromes (ACS) mean that the prevalence and resultant societal economic burden of this disease are projected to increase dramatically. [3]

Patients may present with chest pain, palpitations, shortness of breath, fatigue and peripheral oedema. Management focuses on reducing cardiac work to relieve symptoms and prevent further myocardial damage. Heart failure encompasses a broad range of clinical syndromes and includes stable CHF and acute heart failure (AHF). AHF includes several different phenotypes of varying severity, including de novo AHF, acute decompensated heart failure, hypertensive AHF, AHF with pulmonary oedema and cardiogenic shock (CS). It is worth noting that the improved outcomes that have been achieved over the past 30 years in reducing mortality in CHF have not been replicated in AHF, and outcomes remain relatively poor. [4] Notably, the improvement in outcomes in AHF with CS over this period due to aggressive revascularisation strategies for ACS [5] has lagged behind the improvements seen in septic shock.[6] This comparison points to a poorly researched field with a paucity of randomised trials showing any treatment benefit in AHF. In fact, the treatment armamentarium (comprising diuretics, vasodilators and inotropes) has remained essentially unchanged over the last 30 years.[7] There is, however, increasing interest regarding the use of mechanical circulatory support (MCS) in patients presenting with CS. While high-quality data supporting their use is lacking, outcomes in observational registries suggest better outcomes in patients who are managed in centres using a protocolised approach where early escalation to MCS is adopted.[8]

Patients with AHF may be usefully classified according to their perfusion status *(warm vs. cold)* and the presence or absence of congestion *(wet vs. dry)* (Fig. 33.1). Most patients (>90%) with AHF present with symptoms and signs of congestion. Conversely, only 20% present with symptoms and signs of poor perfusion.[9] First-line management will thus be guided by this initial clinical assessment. Commonly, there is resolution of presenting signs and symptoms in most patients during the index admission. Despite this, the rates of readmission are significant, and 1-year mortality rates remain high with figures ranging from 25% for acute decompensated heart failure[10] to as high as 50% for those presenting with CS.[11]



CONGESTION (–)
CONGESTION (+)
Pulmonary congestion
Orthopnoea/paroxysmal nocturnal dyspnoea
Peripheral (bilateral) oedema
Jugular venous dilatation
Congested hepatomegaly
Gut congestion, ascites
Hepatojugular reflux
HYPOPERFUSION (–)
WARM-DRY
WARM-WET
HYPOPERFUSION (+)
Cold sweated extremities
Oliguria
Mental confusion
Dizziness
Narrow pulse pressure
COLD-DRY
COLD-WET

Hypoperfusion is not synonymous with hypotension, but often hypoperfusion is accompanied by hypotension.

The chart is divided into four quadrants with axes labelled Congestion and Hypoperfusion. The top left quadrant labelled negative congestion and negative hypoperfusion represents warm-dry. The top right quadrant labelled congestion and negative hypoperfusion represents warm-wet. The conditions listed under congestion are pulmonary congestion, orthopnoea/paroxysmal nocturnal dyspnoea, peripheral (bilateral) oedema, jugular venous dilatation, congested hepatomegaly, gut congestion, ascites, hepatojugular reflux. The bottom left quadrant is labelled hypoperfusion and negative congestion represents cold-dry. Conditions listed under hypoperfusion cold sweated extremities, oliguria, mental confusion, dizziness, narrow pulse pressure. The bottom right labelled hypoperfusion and congestion represents cold-wet. Hypoperfusion is not synonymous with hypotension, but often hypoperfusion is accompanied by hypotension.

FIG. 33.1 Classification of patients with acute heart failure according to their perfusion status and the presence or absence of congestion. (Reproduced with permission from Ponikowski P, Voors AA, Anker SD, et al. 2016 ESC Guidelines for the diagnosis and treatment of acute and chronic heart failure: The Task Force for the diagnosis and treatment of acute and chronic heart failure of the European Society of Cardiology (ESC) developed with the special contribution of the Heart Failure Association (HFA) of the ESC. *Eur Heart J* . 2016;37(27):2129–2200. doi:10.1093/eurheartj/ehw128.)

The situation in critical care is further complicated by the involvement of other organ systems. Management in the critical care setting focuses on augmenting global and regional oxygen delivery. However, targeting supranormal physiological parameters has been abandoned as an approach owing to a lack of clinical benefit.[12,13] Management should attempt to resolve the difficult balance between the best interests of the myocardium and the circulatory requirements of the other vital organs. The intensivist should target the minimum necessary oxygen delivery and arterial pressure to maintain other organ function at maximum cardiac efficiency (e.g. ensuring adequate fluid resuscitation before starting inotropic agents) so that cardiac work and the risk of myocardial ischaemia and necrosis from exuberant beta-agonist use are minimised, and the cardiologist should consider the wider circulation and other organ requirements when instituting strategies to protect the myocardium. Despite the known significant side-effect profile of inotropic agents,[14] they remain part of the recommended treatment for incipient or overt CS in international guidelines.[9,15] In practical terms, they should be utilised for hypotensive and hypoperfused patients for the shortest period possible. Despite improving the haemodynamic profile of the patient, no survival benefit has been demonstrated with the use of inotropic agents.[16] Therefore the use of MCS devices may be physiologically beneficial by allowing a reduction in inotrope dose, thus avoiding their detrimental side effect profile. However, given a lack of outcome data and the potential complications of MCS, its use in unselected patients in CS is not yet routinely recommended.[17]

The development of the cardio-renal syndrome in AHF also requires a careful balancing act in critical care. Congestion is thought to be the dominant problem causing increased venous pressure in the kidneys, which further compounds the injurious effects of the low cardiac output (CO) state found in AHF.[18] Fluid removal is therefore key to the improvement of both cardiac and renal function, sometimes at the expense of short-term renal deterioration due to diuretic-induced vasoconstriction, nephrotoxicity and other factors. Judging the degree of acceptable renal injury is often challenging[19] and the presence of diuretic resistance and/or requirement for renal replacement therapy for fluid removal portend a poor outcome.[20]

Diagnosis of Acute Heart Failure

The diagnosis of AHF in critically ill patients is more difficult than is commonly recognised. Although the underlying pathology in most patients with AHF in critical care will be a primary cardiac problem, other diagnoses must also be considered (Box 33.1). Early diagnosis and prompt management are paramount in this potentially life-threatening clinical situation. When a patient presents with suspected AHF, the ‘**CHAMP**’ acronym is a useful tool that can be used at the initial assessment to identify treatable causes (however, this is by no means an exhaustive list):

C : acute **C**oronary syndrome leading to AHF should prompt rapid consideration for percutaneous coronary revascularisation, irrespective of electrocardiogram (ECG) or biomarker changes.

H : **H**ypertensive emergency, commonly presenting as pulmonary oedema, mandates rapid blood pressure reduction initially with vasodilators and diuretics.

A: **A** rrhythmias should be rapidly corrected via pharmacological, electrical or pacing device means as appropriate. However, restoration of normal sinus rhythm may be neither necessary nor achievable; the risks and benefits of each approach should be weighed carefully.

M : acute **M** echanical causes, most commonly occurring as a complication of ACS; for example free wall rupture, ventricular septal defect and acute mitral regurgitation, and due to chest trauma, acute valve incompetence from endocarditis and aortic dissection, necessitate either surgical or percutaneous approaches for repair.

P : acute **P** ulmonary embolism (PE) leading to obstructive shock dictates a high risk of early death and requires either systemic or localised catheter-directed thrombolysis. Surgical options are rarely undertaken. The management of haemodynamically stable patients with PE requires further risk stratification using echocardiography and/or CT imaging, troponin measurement and assessment of clinical parameters. Anticoagulation should be commenced without delay in low- and intermediate-risk groups. Thrombolysis is generally reserved as a rescue therapy for patients with haemodynamic deterioration despite anticoagulation. Catheter-directed thrombolysis utilising lower doses of thrombolytic agents is emerging as a helpful treatment in selected patient groups with higher-risk features; robust trial data is currently lacking. [21]

Coronary artery disease/acute coronary syndrome (ACS)
Cardiac arrhythmias – atrial fibrillation (AF)
Infection – systemic sepsis, viral myocarditis
Mechanical – endocarditis, pulmonary emboli, valve problems, septal defects, tamponade, high intrathoracic pressure with

inadequate preload
Drugs – beta-blockers, calcium antagonists, cytotoxic drugs (e.g. doxorubicin), alcohol, cocaine
Hypoxaemia
Metabolic – acidaemia, thiamine deficiency, thyrotoxicosis, hypocalcaemia, hypophosphataemia
Myocardial contusion – blunt thoracic trauma
Myocardial infiltration – tumour, sarcoidosis, amyloidosis
Vasculitis
Neuromuscular conditions – Duchenne muscular dystrophy, Friedrich ataxia, myotonic dystrophy

It is also important to critically reassess the patient referred with a diagnosis of AHF to decide whether this is indeed the primary problem. The history, examination and initial investigations with routine blood tests, ECG and chest radiograph may be compatible with this diagnosis, but many such patients are elderly with multiple comorbidities, and deciding whether the patient is suffering from a primary myocardial pathology as opposed to a pulmonary problem or indeed systemic sepsis can be difficult. Equally, patients believed to have a primary respiratory problem may fail to wean from ventilatory support because of a failure to realise that they have left ventricular (LV) failure with a high left atrial pressure (LAP) and incipient pulmonary oedema, causing a reduction in pulmonary compliance, an increased work of breathing and respiratory distress when positive pressure is withdrawn.

Further investigations that can help to confirm or refute an initial diagnosis of AHF are echocardiography and the measurement of biomarkers, such as natriuretic peptides and cardiac troponins.

Echocardiography (see Chapter 25)

Echocardiography is an essential investigation in the management of critically ill patients with AHF [9, 22] and the modern intensivist should at least be able to perform a focused examination.

Echocardiography will frequently establish the underlying cardiac pathology and can be used to monitor the response to treatment. It will:

1. Identify increased LV end-systolic and diastolic dimensions, indicating ventricular contractile failure; termed systolic dysfunction or heart failure with reduced ejection fraction (HFrEF), [9] HFrEF is defined as an ejection fraction (EF) less than or equal to 40%. However, the use of EF as an index of ventricular contractility can be misleading, especially in critically ill patients on vasopressors and inotropic drugs, as it is dependent on both preload and afterload. Therefore, EF should be interpreted in the context of LV loading conditions and any structural changes that lead to alterations in LV end-diastolic volume. [22, 23] The typical pitfalls with sole reliance on EF are the failure to appreciate the presence of excess afterload (e.g. vasopressor use) and augmented preload (e.g. mitral regurgitation) which leads to an underestimate of true LV systolic function; conversely, the EF can overestimate true LV systolic function in certain pathologies e.g. LV hypertrophy.
2. Identify diastolic dysfunction as a consequence of impaired ventricular relaxation, also termed heart failure with preserved ejection fraction (HFpEF). HFpEF is defined as an EF greater than or equal to 50% often in the context of increased LV wall thickness and/or left atrial enlargement. Preserved EF in this context does not necessarily equate to an adequate CO, [24] and high-pressure preload measurements may fail to reflect the true volume preload and the potential need for extra fluid volume. Approximately 50% of patients with heart failure have HFpEF, or mid-range EF (HFmrEF, with EF of 41% to 49%), and these patients tend to have a history

of hypertension and/or present in a hypertensive state and are often obese.[9,25] Outcomes for patients with HFpEF and HFmrEF are similarly poor to those with HFrEF, but the reasons for this reflect a combination of the absence of proven therapies for the former groups and the sequelae of their non-cardiovascular comorbidities.[26] Therefore the arbitrary cut-offs that define HFpEF, HFmrEF and HFrEF should not deter a thorough clinical assessment of the patient to allow an individualised approach to the treatment of the particular AHF phenotype and management of other end-organ dysfunction.[27,28]

3. Identify the presence of a pericardial effusion and determine whether ventricular filling is impaired (cardiac tamponade) and whether drainage is indicated. However, ultimately, tamponade is a clinical diagnosis based on the full haemodynamic picture in the context of pericardial fluid demonstrated on the echocardiogram. Many of the diagnostic features related to alterations with respiration are affected by positive-pressure ventilation, and drainage may be appropriate even if such classic echocardiographic criteria are not present. Even small effusions may cause tamponade since it is the rate of accumulation of fluid rather than the amount of fluid that determines the degree of cardiac compromise.
4. Identify obstruction to cardiac filling from other intrathoracic space-occupying lesions that increase intrathoracic pressure, particularly in ventilated patients (pleural effusions, alveolar gas trapping in asthma).
5. Assess adequacy of volume preload of LV, particularly in the context of raised preload pressures; assess fluid responsiveness and monitor the effects of a fluid challenge. The left ventricular outflow tract velocity time integral (LVOT VTI) is an easily measurable surrogate of stroke volume, and therefore cardiac output, in the absence of significant LVOT abnormalities and can be used to assess response to treatment.[29]
6. Identify primary valvular heart disease (critical aortic stenosis, acute mitral regurgitation from papillary muscle rupture and acute endocarditis) when urgent surgery is indicated, and distinguish this

from functional valvular regurgitation due to primary ventricular disease for which surgery could be lethal.

7. Identify septal defects, regional wall motion abnormalities and aneurysmal dilation from recent or previous myocardial infarction.
8. Identify the presence of intracardiac thrombus.
9. Identify pulmonary hypertension (PH) associated with tricuspid regurgitation when an estimate of pulmonary artery (PA) systolic pressure can be made.
10. Identify right ventricular (RV) size and function and discriminate between pressure and volume overload of the RV. The presence of RV dysfunction also can be used to diagnose and risk stratify patients presenting with suspected acute PE. Tricuspid annular plane systolic excursion (TAPSE) is a simple and quick measure of longitudinal RV systolic function; a value of 17 mm or less reflects impaired function. [30]

Measurement of Natriuretic Peptides and Cardiac Troponins

Myocardial injury and the development of AHF are common, but frequently unrecognised complications of critical illness occurring not only in patients with an overt ACS but also in other conditions, such as sepsis and massive PE. [31] Relying on blood tests alone to establish a diagnosis or to plan management is inadvisable but, when interpreted in conjunction with the wider clinical picture, natriuretic peptides and cardiac troponins appear to be sensitive markers of myocardial stress and necrosis.

Natriuretic Peptides

B-type natriuretic peptide (BNP) and *N* -terminal pro B-type natriuretic peptide (NT-proBNP) are the most commonly measured natriuretic peptides in clinical practice. Mid-regional pro-atrial natriuretic peptide (MR-proANP) has also been isolated, and measured, and there is growing interest in its use as a biomarker. [32] The main stimulus for natriuretic peptide synthesis and release is myocardial wall stress; cardiac myocytes release the prohormone, proBNP, which is subsequently cleaved into biologically active BNP and the inactive *N* -terminal fragment (NT-proBNP). Although natriuretic peptide release appears to be related to end-diastolic volume and pressure, it does not reliably differentiate between HFrEF and HFpEF or accurately predict EF or filling pressures.[33] Measurement of BNP and NT-proBNP in the emergency department may discriminate patients with heart failure from those with pulmonary or other non-cardiac causes for acute dyspnoea.[34] Routine measurement of natriuretic peptides is recommended by several international heart failure guidelines.[9,35,36] Studies have demonstrated that, at a cut-off of 100 pg/mL, BNP has a sensitivity of 90% and a specificity greater than 70% as a test for excluding heart failure.[37] Similar data have also been reported for NT-proBNP with a cut-off value of 300 pg/mL.[38] BNP and NT-proBNP have high negative predictive values but lower positive predictive values; therefore their main utility is to rule out the diagnosis of heart failure in both the acute and non-acute setting. There are a number of cardiovascular and non-cardiovascular causes of raised natriuretic peptides including atrial fibrillation (AF), increasing age and acute or chronic kidney disease. BNP has also been shown to be a marker of myocardial dysfunction and prognosis in severe sepsis.[39] Therefore elevated levels of natriuretic peptides should prompt further cardiac investigation, specifically echocardiography. Despite their prognostic significance, a natriuretic-guided approach to CHF therapy titration has not been shown to be more effective than standard care in high-risk patients with HFrEF.[40]

Cardiac Troponins

Troponins are regulatory proteins that form part of the thin filament of the myocyte contractile apparatus (in addition to actin and tropomyosin); three subunits have been identified: (1) Troponin I (TnI), which binds actin to inhibit actin–myosin interaction; (2) Troponin T (TnT), which binds tropomyosin; and (3) Troponin C (TnC), which binds calcium ions resulting in a conformational change in the troponin–tropomyosin complex thus exposing myosin-binding sites. The cardiac isoforms, cTnI and cTnT, are specific to the heart and can be measured in the blood after myocyte necrosis with 50% release by 4 hours, peaking at 12–24 hours and remaining elevated for up to 10 days. They are far more sensitive than traditional cardiac enzyme tests, such as creatine kinase, and have substantially changed the definition, diagnosis and management of acute myocardial infarction (AMI). Recent advances have led to the routine use of high-sensitivity cardiac troponin assays to increase diagnostic accuracy for AMI at an earlier time point as compared with conventional assays; their use is now routine and advocated in current guidance.[41, 42]

Cardiac troponins may be released in conditions other than acute coronary ischaemia,[43] such as sepsis, and after chemotherapy, and in the absence of evidence of myocardial necrosis, as in AHF or major PE, where it is believed that the acute ventricular dilation causes increased membrane permeability. Raised troponin levels are also associated with increased morbidity and mortality in surgical ICU patients[44–46] and in patients presenting with acute decompensated heart failure.[47, 48]

Elevated levels of cardiac troponins, BNP and NT-proBNP, may also be detected in the presence of RV dysfunction following an acute PE. They can be used to risk stratify patients owing to their high negative predictive value for in-hospital death and adverse events. In haemodynamically stable patients, normal values indicate a lower risk of adverse outcome; therefore, less aggressive therapy may be warranted.[21]

Raised levels of these markers, indicating early myocardial stress, may have an important role in alerting the clinician to impending myocardial failure and the need to review the use of drugs that stimulate the myocardium, and to consider the introduction of a beta-blocker, particularly in the context of tachycardia.

It should be remembered that, for critically ill patients with AHF not resulting from primary myocardial infarction, if the precipitating cause is successfully treated without significant myocardial necrosis occurring the AHF will resolve, cardiac function will return to its premorbid state and the prognosis will be improved.

The remainder of this chapter addresses the assessment and principles of management of ventricular function in patients admitted to critical care with AHF.

Circulatory Failure or ‘Shock’ (see Chapter 23)

The principal function of the heart is the generation of the energy necessary to perfuse the lungs with venous blood and to propel the oxygenated arterial blood through the systemic circulation at a rate and pressure that ensure that the fluctuating metabolic requirements of the various organs are met at rest and during exercise. This should be performed at maximum efficiency so that the work performed is not at the cost of unnecessarily high myocardial energy expenditure and the risk of myocardial ischaemia is minimised.

Failure to maintain an adequate oxygen supply to the tissues with the consequent development of anaerobic cellular metabolism defines circulatory failure or ‘shock’, a term that benefits from brevity but little else since it implies neither cause nor prognosis, but its use is now widespread and inescapable. Box 33.2 classifies circulatory ‘shock’.

Box 33.2

Major categories of circulatory failure or ‘shock’

Cardiogenic – myocardial infarction, myocarditis, vasculitis, valve dysfunction (e.g. critical aortic stenosis, mitral regurgitation and acute endocarditis), post-cardiac-bypass surgery, drug overdose (beta-blockers, calcium antagonists)

Hypovolaemic – haemorrhage, burns, gastrointestinal fluid loss

Obstructive – pulmonary embolus, cardiac tamponade and tension pneumothorax

Anaphylactic – drugs, blood transfusion and insect sting

Septic – bacterial infection, non-infective inflammatory conditions (e.g. pancreatitis, burns and trauma)

Neurogenic – intracranial haemorrhage, brainstem compression and spinal cord injury

A detailed overview of shock is covered in Chapter 23 , however, several points require particular emphasis here:

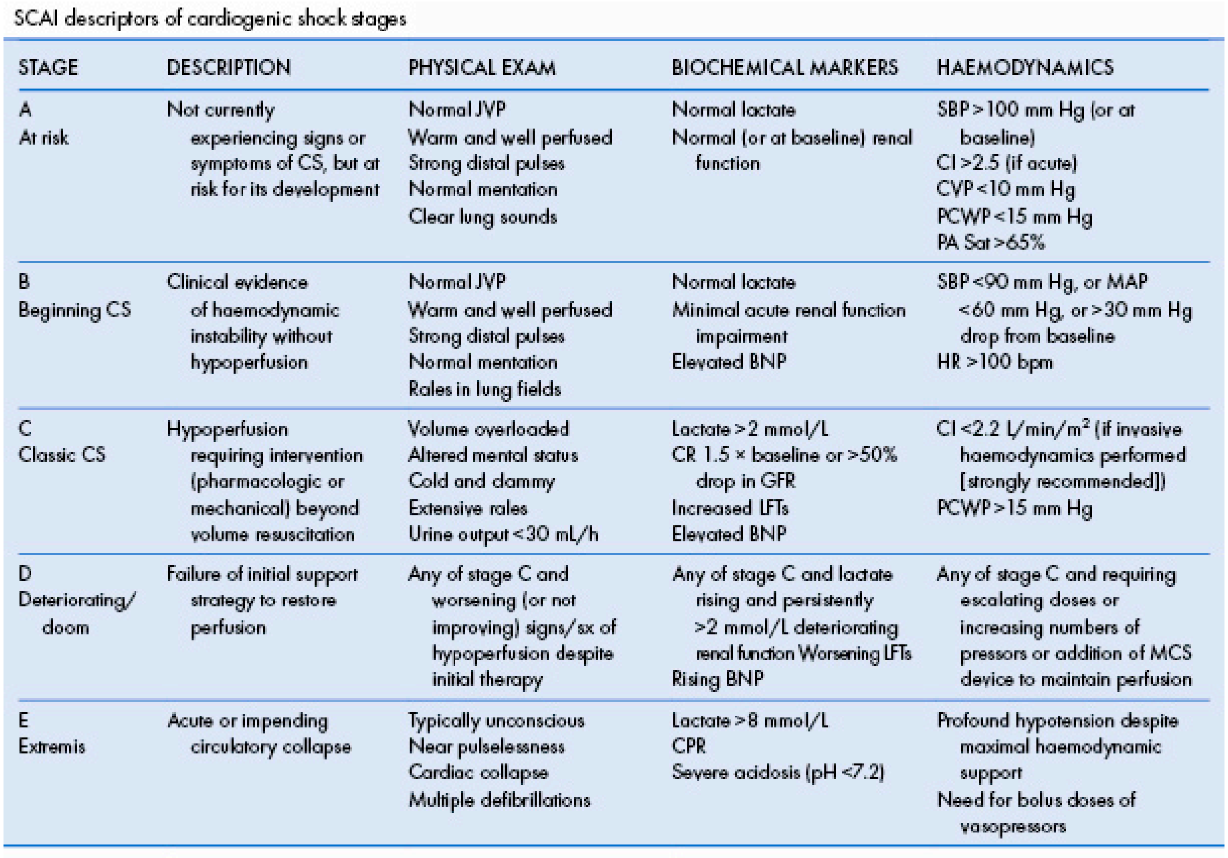
1. AHF resulting in CS is not a pathological diagnosis but a collective term that embraces all causes of myocardial failure. Treatment must focus on the underlying diagnosis.
2. Patients admitted to critical care may have AHF either as the primary reason for admission (e.g. following AMI), or develop it as part of multiple organ failure triggered by an extra-cardiac cause such as severe sepsis resulting in myocardial dysfunction.
3. Pre-existing cardiac disease, usually ischaemic heart disease, is an important factor in determining the physiological response to critical illness. Several studies investigating the effect of manipulating oxygen delivery have demonstrated the poor prognosis associated with the inability of the heart to achieve a hyperdynamic response to critical illness either spontaneously or with volume loading and inotropic support.[12], [13]
4. Although hypotension is often considered to be the cardinal sign of circulatory failure, other global features (persistent tachycardia, confusion, tachypnoea, impaired peripheral perfusion and progressive metabolic acidaemia) occur earlier since the body has powerful homeostatic mechanisms that maintain pressure at the expense of flow.
5. The heart must provide its own blood supply, and if coronary blood flow does not match myocardial oxygen requirements coronary ischaemia develops, and cardiac and global circulatory failure may ensue.
6. Early intervention in circulatory shock has a major impact on survival.[49] If treatment is delayed until organ failure is established, the underlying pathological processes are frequently irreversible.

Society for Cardiovascular Angiography and Interventions Classification

The Society for Cardiovascular Angiography and Interventions (SCAI) have recently proposed a schema for the diagnosis of CS shock. This aims to provide a common language by using a simple and rapid framework for assessment of patients across clinical settings, to facilitate timely involvement of a CS multi-disciplinary team (CS-MDT) and associated therapies.

The classification describes five stages of escalating severity (A to E), along with descriptors based on clinical findings, biochemical markers and haemodynamic profile (Table 33.1). While this provides a helpful common language, the prognostic influence of such a classification remains to be seen.

Table 33.1



SCAI descriptors of cardiogenic shock stages

STAGE	DESCRIPTION	PHYSICAL EXAM	BIOCHEMICAL MARKERS	HAEMODYNAMICS
A At risk	Not currently experiencing signs or symptoms of CS, but at risk for its development	Normal JVP Warm and well perfused Strong distal pulses Normal mentation Clear lung sounds	Normal lactate Normal (or at baseline) renal function	SBP > 100 mm Hg (or at baseline) CI > 2.5 (if acute) CVP < 10 mm Hg PCWP < 15 mm Hg PA Sat > 65%
B Beginning CS	Clinical evidence of haemodynamic instability without hypoperfusion	Normal JVP Warm and well perfused Strong distal pulses Normal mentation Rales in lung fields	Normal lactate Minimal acute renal function impairment Elevated BNP	SBP < 90 mm Hg, or MAP < 60 mm Hg, or > 30 mm Hg drop from baseline HR > 100 bpm
C Classic CS	Hypoperfusion requiring intervention (pharmacologic or mechanical) beyond volume resuscitation	Volume overloaded Altered mental status Cold and clammy Extensive rales Urine output < 30 mL/h	Lactate > 2 mmol/L CR 1.5 × baseline or > 50% drop in GFR Increased LFTs Elevated BNP	CI < 2.2 L/min/m^2 (if invasive haemodynamics performed [strongly recommended]) PCWP > 15 mm Hg
D Deteriorating/ doom	Failure of initial support strategy to restore perfusion	Any of stage C and worsening (or not improving) signs/sx of hypoperfusion despite initial therapy	Any of stage C and lactate rising and persistently > 2 mmol/L deteriorating renal function Worsening LFTs Rising BNP	Any of stage C and requiring escalating doses or increasing numbers of pressors or addition of MCS device to maintain perfusion
E Extremis	Acute or impending circulatory collapse	Typically unconscious Near pulselessness Cardiac collapse Multiple defibrillations	Lactate > 8 mmol/L CPR Severe acidosis (pH < 7.2)	Profound hypotension despite maximal haemodynamic support Need for bolus doses of vasopressors

From Baran DA, Grines CL, Bailey S, et al. SCAI clinical expert consensus statement on the classification of cardiogenic shock: This document was endorsed by the American College of Cardiology (ACC), the American Heart Association (AHA), the Society of Critical Care Medicine (SCCM) and the Society of Thoracic Surgeons (STS) in April 2019. *Catheter Cardiovasc Interv* . 2019;94(1):29-37. doi: 10.1002/ccd.28329 .

BNP, B-type natriuretic peptide; *CI,* cardiac index; *CPR,* cardiopulmonary resuscitation; *CR,* creatinine; *CS* , cardiogenic shock; *CVP,* central venous pressure; *GFR,* glomerular filtration rate; *HR,* heart rate; *JVP,* jugular venous pressure; *LFTs,* liver function tests; *MAP,* mean arterial pressure; *MCS,* mechanical circulatory support; *PA Sat,* pulmonary arterial saturation; *PCWP,* pulmonary capillary wedge pressure; *SBP,* systolic blood pressure.

The SCAI classification emphasises the rapidly dynamic nature of patients with CS. Therefore a CS-MDT should be involved early in the course of disease. Such an approach, when coupled with advanced haemodynamic monitoring, and MCS in selected cases, has been shown to improve survival from approximately 50% to 70%–75% in some observational cohorts.[50], [51]

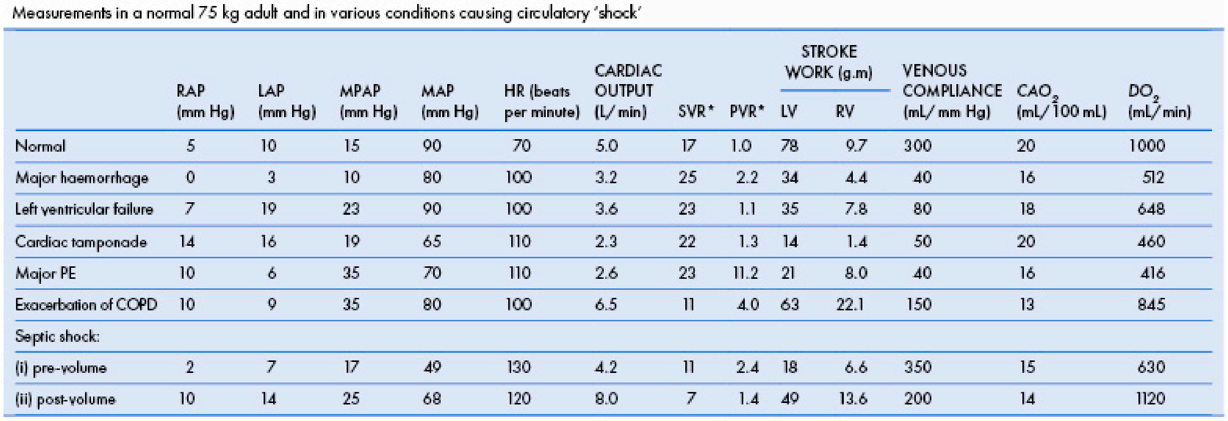
Assessment of Ventricular Function

Making the considerable assumption that the circulation can be analysed as a constant-flow fixed-compliance system, six key measurements traditionally define ventricular performance:

- right and left atrial pressures (RAP, LAP) or ventricular preload
- mean systemic and pulmonary arterial pressures (MAP, PAP) or ventricular afterload
- heart rate (HR)
- CO

Table 33.2 illustrates typical values in normal subjects and in the common causes of circulatory failure with the calculation of the associated vascular resistances and oxygen delivery. The values quoted are merely examples that indicate the pattern of circulatory derangement produced by these pathologies: pre-existing cardiopulmonary disease and the severity of the condition will affect the precise figures obtained in individual cases and the response to vasoactive therapy.

Table 33.2



Measurements in a normal 75 kg adult and in various conditions causing circulatory 'shock'

	RAP (mm Hg)	LAP (mm Hg)	MPAP (mm Hg)	MAP (mm Hg)	HR (beats per minute)	CARDIAC OUTPUT (L/ min)	SVR*	PVR*	STROKE WORK (g.m)		VENOUS COMPLIANCE (mL/ mm Hg)	CAO_2 (mL/ 100 mL)	DO_2 (mL/ min)
									LV	RV			
Normal	5	10	15	90	70	5.0	17	1.0	78	9.7	300	20	1000
Major haemorrhage	0	3	10	80	100	3.2	25	2.2	34	4.4	40	16	512
Left ventricular failure	7	19	23	90	100	3.6	23	1.1	35	7.8	80	18	648
Cardiac tamponade	14	16	19	65	110	2.3	22	1.3	14	1.4	50	20	460
Major PE	10	6	35	70	110	2.6	23	11.2	21	8.0	40	16	416
Exacerbation of COPD	10	9	35	80	100	6.5	11	4.0	63	22.1	150	13	845
Septic shock:													
(i) pre-volume	2	7	17	49	130	4.2	11	2.4	18	6.6	350	15	630
(ii) post-volume	10	14	25	68	120	8.0	7	1.4	49	13.6	200	14	1120

Typical circulatory measurements in a normal adult and in various cardiorespiratory conditions that may cause shock. The severity of the condition and pre-existing cardiorespiratory disease will affect the precise figures obtained in individual cases.

Pressures referenced to zero at fifth intercostal space, mid-axillary line in supine patient.

SVR*/PVR* × 80 to give SI units: $\text{dyn}\cdot\text{s}\cdot\text{cm}^{-5}$.

CaO_2 , Arterial oxygen content; *COPD* , chronic obstructive pulmonary disorder; *DO_2* , global oxygen delivery; *HR* , heart rate; *LAP* , left atrial pressure; *LV* , left ventricle; *mPAP/MAP* , mean pulmonary artery/arterial pressure; *PE* , pulmonary embolism; *PVR* , pulmonary vascular resistance; *RAP* , right atrial pressure; *RV* , right ventricle; *SVR* , systemic vascular resistance.

Stroke volume (SV) is calculated from CO and HR:

$$SV = \frac{CO}{HR}.$$

.

Three factors determine stroke volume: (1) preload, (2) afterload and (3) myocardial contractility.

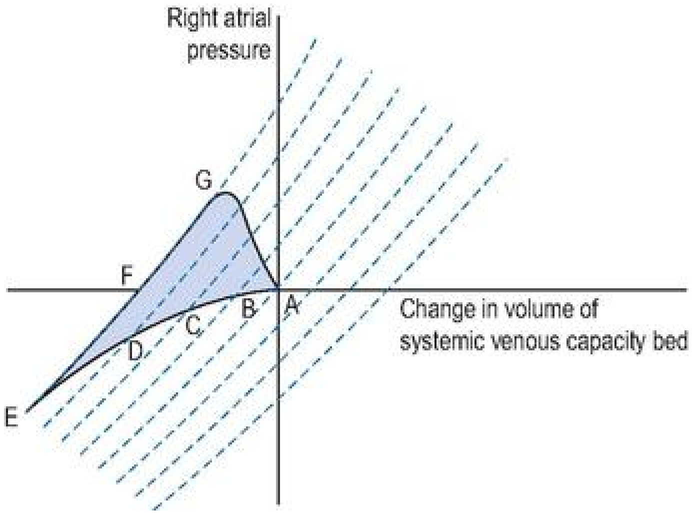
Ventricular Preload

Ventricular preload, traditionally assessed from atrial filling pressures, determines the end-diastolic ventricular volume, which, according to Starling’s law of the heart, and depending on ventricular contractility, dictates the stroke work generated by each ventricle at the next cardiac contraction. The resulting stroke volume depends on the resistance or afterload that confronts the ventricle.

In the general ward, the jugular venous pressure is measured from the sternal angle; however, in the ICU, vascular pressures are measured from the mid-axillary line in the fifth intercostal space. From this reference point, in the supine position, the normal RAP is between 2 and 8 mm Hg, but may also approximate to zero, and the LAP is between 4 and 12 mm Hg. Relative changes in either the contractility of the two ventricles or the respective vascular resistances will change the relationship between the atrial pressures, which must then be independently assessed.

The predominant factor determining preload is venous return, which depends on the intravascular volume and venous tone, which is controlled by the autonomic nervous system, circulating catecholamine levels and local factors, particularly PO_2, PCO_2 and pH.

The systemic venous bed is the major intravascular capacitance or reservoir of the circulation with a compliance that can vary from 30 to over 300 mL/mm Hg and which provides a buffer against the effects of intravascular volume loss. It also explains the response observed in major haemorrhage and subsequent transfusion. As volume is lost, venous tone increases, preventing the large falls in atrial filling pressures and CO that would otherwise occur. If the equivalent volume is returned over the subsequent few hours, the RAP gradually returns to normal as the intravascular volume is restored and the reflex increase in sympathetic tone abates. However, rapid re-infusion of the same volume does not allow sufficient time for the venous and arteriolar tone to fall and may result in the LAP rising to a level that precipitates pulmonary oedema, although the intravascular volume has only been returned to the pre-haemorrhage level and LV function is normal (Fig. 33.2).



The graph features two axes. The vertical axis reads Right Atrial Pressure and extends upward. The horizontal axis reads Change in Volume of Systemic Venous Capacity Bed and extends to the right. A curved line on the graph starts at point A near the origin, moves through points B, C, D, E, and F, and ends at point G in an anticlockwise direction, which forms a loop. Points A through G appear in sequence along the curve. Diagonal lines radiate from the origin at various angles, which intersect the curve at different points to indicate pressure-volume relationships.

FIG. 33.2 Venous compliance curves: each *dotted line* represents a line of constant venous compliance ranging from low compliance (increased tone) on the left to increased compliance (reduced tone) on the right. Line ABCDE shows the effect of progressive haemorrhage with the reduction in venous compliance limiting the fall in atrial pressure. Line EFGA shows the effect of rapid reinfusion of the same volume that was removed, but at a rate that does not allow the sympathetically mediated increase in venous tone to abate.

If the preload is low and either blood pressure or CO is inadequate, the priority is volume loading to restore intravascular volume and venous return.

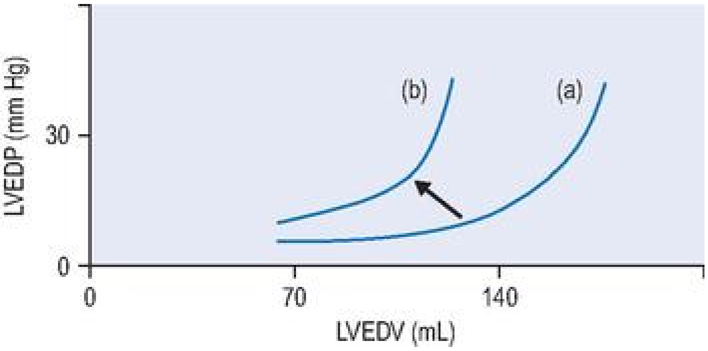
Raised preload pressures reflect: (1) high intravascular volume, (2) impaired myocardial contractility or (3) increased afterload.

Preload may be reduced by:

- removing volume from the circulation (diuretics, venesection and renal replacement therapy) or increasing the capacity of the vascular bed with venodilator therapy (e.g. glyceryl trinitrate and morphine). Caution is advised with the use of morphine in this regard as the deleterious effects on respiratory and cognitive function can offset useful vasodilation. [52]
- improving contractility
- reducing afterload

In assessing preload, end-diastolic volume rather than pressure is relevant and when interpreting atrial pressures as measures of preload, two points must be considered:

1. Intravascular pressure (P v) measurements are misleading if the intrathoracic pressure (P t) is raised since the true distending pressure that determines ventricular end-diastolic volume is the transmural pressure (P v– P t). This is particularly relevant if there is significant alveolar gas trapping generating intrinsic positive end-expiratory pressure (PEEP), as seen in asthma; in positive-pressure ventilation with high PEEP levels; and when an inverse inspiratory-to-expiratory time ratio is used.
2. When the ventricle is poorly compliant, as in diastolic dysfunction, the end-diastolic pressure–volume relationship ceases to exhibit the approximately linear relationship over the normal physiological range of ventricular filling volumes (Fig. 33.3). Under these conditions, pressure will not necessarily reflect the adequacy of volume preload.



The graph features two axes. The vertical axis reads Left Ventricular End Diastolic Pressure in millimetres of mercury and extends from zero to thirty. The horizontal axis reads Left Ventricular End Diastolic Volume in millilitres and extends from zero to one hundred forty. Two curves appear on the graph. The curve labelled a starts at 70, rises gradually, and then steepens as it approaches one hundred forty millilitres. The curve labelled b also starts at 70, rises more steeply than curve a, and intersects an arrow that points from curve a to curve b.

FIG. 33.3 End-diastolic pressure-volume relationship (EDPVR) curves: (A) normal heart; (B) diastolic dysfunction. In the context of reduced ventricular compliance, the EDPVR curve shifts upward and to the left. *LVEDP* , Left ventricular end-diastolic pressure; *LVEDV* , left ventricular end-diastolic volume. (Modified from Brandis K. *The Physiology Viva* . 1997 Alderbury House.)

Ventricular Afterload

The vascular resistance against which each ventricle works is calculated, by analogy with Ohm's law, as the pressure gradient across the vascular bed divided by the CO (Box 33.3).

Box 33.3

Calculation of ventricular afterload and stroke work

Systemic vascular resistance (SVR)	$= [(\text{MAP} - \text{RAP})/\text{CO}] \times 80$ dyn.s.cm^{-5}
	$= [(90 - 5)/5] \times 80 = 1360$ dyn.s.cm^{-5}
SVRI	$= \text{SVR} \times \text{BSA} = 1360 \times 1.65 = 2244$ dyn.s.cm^{-5}.m^{-2}
Pulmonary vascular resistance (PVR)	$= [(\text{mPAP} - \text{LAP})/\text{CO}] \times 80$ dyn.s.cm^{-5}
	$= [(15 - 10)/5] \times 80 = 80$ dyn.s.cm^{-5}
PVRI	$= \text{PVR} \times \text{BSA} = 80 \times 1.65 = 132$ dyn.s.cm^{-5}.m^{-2}
Stroke volume (SV)	= CO/HR = 72 mL
Stroke volume index (SVI)	= 72/1.65 = 44 mL/m^{2}
Ventricular stroke work (VSW)	= SV × (afterload − preload)
LVSW	$= \text{SV} \times (\text{MAP} - \text{LAP}) \times 0.0136$ g.m
	$= 72 \times (90 - 10) \times 0.0136 = 78$ g.m
LVSWI	= 78/1.65 = 47 g.m/m^{2}
RVSW	$= \text{SV} \times (\text{mPAP} - \text{RAP}) \times 0.0136$ g.m
	$= 72 \times (15 - 5) \times 0.0136 = 10$ g.m
RVSWI	= 10/1.65 = 6 g.m/m^{2}

Pressures are measured in mm Hg, CO in L/min. Values for resistance and stroke work are frequently indexed using the patient’s BSA derived from height and weight. In calculating ventricular stroke work, 0.0136 converts to SI units of g.m. Example calculations assume a normal 75 kg individual with BSA 1.65 m ^{2} .

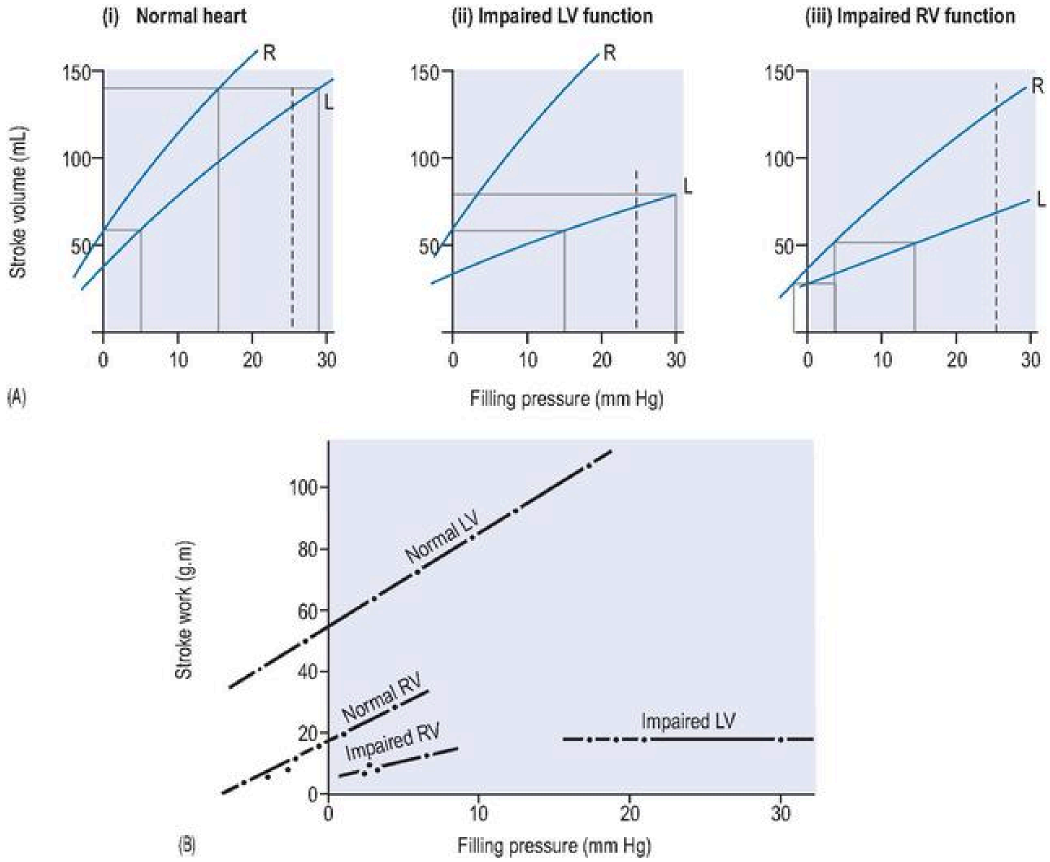
BSA , Body surface area; *CO* , cardiac output; *HR* , heart rate; *LAP* , left atrial pressure; *LVSW* , left ventricular stroke work; *LVSWI* , left ventricular stroke work index; *MAP* , mean systemic pressure; *mPAP* , mean pulmonary arterial pressure; *PVR* , pulmonary vascular resistance; *PVRI* , pulmonary vascular resistance index; *RAP* , right atrial pressures; *RVSW* , right ventricular stroke work; *RVSWI* , right ventricular stroke work index; *SV* , stroke volume; *SVR* , systemic vascular resistance; *SVRI* , systemic vascular resistance index.

If ventricular work is constant, increased vascular resistances produce higher pressures but with a lower CO. A systemic vasodilator such as sodium nitroprusside will reduce systemic resistance and blood pressure and increase CO. Although such manipulation is attractive in increasing CO for the same cardiac work, it is important to maintain a blood pressure that ensures appropriate distribution of blood flow and a diastolic pressure sufficient to maintain coronary artery perfusion, particularly in patients with known ischaemic heart disease or pre-existing hypertension.

The haemodynamic effects of commonly used vasoactive agents are covered in Chapter 26 .

Ventricular Contractility and Efficiency

The work that the ventricle performs under given loading conditions defines contractility. For each ventricle it may be expressed mathematically as the gradient and intercept of the relationship between atrial filling pressure and stroke work (Fig. 33.4). The resulting stroke volume varies with the resistance of the vascular bed into which the ventricle is ejecting. Although the RV generates a much smaller stroke work, the afterload (pulmonary vascular resistance, PVR) against which it ejects is correspondingly lower as the RV and LV stroke volumes must necessarily be the same over time.



The set of four graphs consists of two sections labelled A and B. Section A includes three graphs from left to right. The first graph, labelled Normal heart, plots stroke volume in millilitres on the vertical axis from zero to one hundred fifty against fill pressure in millimetres of mercury on the horizontal axis from zero to thirty. Two curves labelled R and L rise sharply. The second graph, labelled Impaired Left Ventricular function, uses the same axes and plots two curves labelled R and L, where curve L rises more gradually. The third graph, labelled Impaired Right Ventricular function, uses the same axes and plots two curves labelled R and L, where curve R rises more gradually. Section B contains one graph that plots stroke work in gram metres on the vertical axis from zero to eighty against fill pressure in millimetres of mercury on the horizontal axis from zero to thirty. Four lines labelled Normal Left Ventricular, Normal Right Ventricular and Impaired Right Ventricular appear with various slopes. Impaired Left Ventricular function appears horizontally.

FIG. 33.4 Ventricular function curves: (A) Relationship between stroke volume (mL) and atrial filling pressure for left (L) and right (R) ventricles in patients with normal and impaired ventricular function; (B) Relationship between stroke work (g.m.) and atrial filling pressure (in mm Hg) for the left (L) and right (R) ventricles for a normal subject and a patient with severe left and right ventricular failure.

The work generated by each ventricle with each heartbeat is the ventricular stroke work and is calculated as shown in Box 33.3 .

Consideration of ventricular work is important since optimum circulatory management requires that the necessary pressures and flows to maintain satisfactory organ perfusion and oxygen delivery are achieved at maximum cardiac efficiency (i.e. for the minimum ventricular work to avoid myocardial ischaemia). Furthermore, LV efficiency is the ratio of work output to energy input and may be less than 20% in patients with AHF, with over 80% of energy lost as heat.

If circulatory failure is due to impaired myocardial contractility, as defined by a ‘flattened’ stroke work/filling pressure equation (see Fig. 33.4), the atrial pressures will often already be raised. Provided such pressures reflect volume preload, further increases are not helpful since the ventricle becomes increasingly distended with high wall tension, as predicted by Laplace’s law:

$$\text{wall tension} = (\text{intraventricular pressure} \times \text{radius}) \div (\text{wall thickness} \times 2)$$

This increase in wall tension compromises myocardial blood supply, particularly epicardial to endocardial blood flow, resulting in endocardial ischaemia, further impairment of ventricular contractility and the risk of pulmonary oedema developing.

The remaining therapeutic options are:

- *Reduce afterload* using an arteriolar dilator (nitrates, alpha-blockers, phosphodiesterase-3 (PDE-3) enzyme inhibitors, angiotensin-converting enzyme (ACE) inhibitors), although this strategy is frequently limited by the resulting fall in systemic pressure.
- *Increase myocardial contractility* , either by removing negatively inotropic influences (acidaemia, hyperkalaemia and drugs) or by using a positive inotropic agent, which may be defined as an agent that increases the gradient of the stroke work to filling pressure relationship, resulting in a larger stroke volume for the same preload and afterload pressures. When considering the use of an inotropic agent, the adverse effects of vasoactive agents on ventricular efficiency, metabolic rate and regional distribution of flow should be considered in addition to their pro-arrhythmogenic tendencies.

Heart Rate and Rhythm

In cardiac failure, the stroke volume is usually constant for rates up to 100/min and thereafter falls as restriction of diastolic filling time limits end-diastolic volume. Increasing the HR from 70 to 90/min will increase CO by almost 30%. Achieving this with a chronotrope such as the beta$_1$-agonist isoprenaline increases myocardial work and oxygen consumption and also ventricular irritability.

Consideration should be given to controlling HRs above 110/min, particularly if the rhythm is irregular, using drugs or DC cardioversion and ensuring that plasma potassium and magnesium levels are corrected. In chronic and stable HFrEF, beta-blockers are recommended to reduce the risk of hospitalisation and death.[9] Caution is warranted if using beta-blockers in AHF owing to their negatively inotropic properties; and beta-blockers are usually contraindicated if the patient is in CS, where an elevated heart rate is often compensatory. Digoxin is appropriate for rate control in AF and has a temporary positive inotropic effect.[53] Amiodarone is suitable for all supraventricular rhythms and is more likely to restore sinus rhythm. However, it is a negative inotrope, and this can be significant in patients with severe heart failure.

Assessment of Myocardial Function

Of the six key circulatory variables that define ventricular function, three (RAP, MAP and HR) can be assessed clinically and are routinely monitored in ICU patients. However, additional monitoring is required to, directly or indirectly, measure the other three variables (LAP, PAP and CO) to answer the following questions:

1. Is further intravascular volume indicated?
2. Is CO too low and compromising global oxygen delivery?
3. Is dilator, constrictor or inotropic therapy appropriate?

It is certainly not always necessary to use invasive monitoring. Initial management can be based on clinical assessment of intravascular volume and CO. The discipline of committing to an estimate of these key variables ensures that both the analysis of the circulation and the approach to treatment are logical. Further monitoring should be instituted if the initial management does not produce clinical improvement. Alternative, less invasive methods are also available for assessing intravascular volume status and CO to guide therapy; echocardiography,[22,54] oesophageal Doppler,[55] lithium dilution (LiDCO),[56] transpulmonary thermodilution with pulse contour analysis (PiCCO)[57] and arterial pressure waveform analysis.[58–60] Such techniques can also provide data on volume rather than pressure preload of the LV, in addition to dynamic measures of CO (see Chapter 24).

Key Points When Assessing Cardiac Function

1. Pressure is no guarantee of flow.
2. Trends and changes are more important than a single observation.
3. Dynamic tests (e.g. assessing stroke volume response or a change in pulse pressure or stroke volume variation to a fluid challenge) are more revealing than static tests (e.g. central venous pressure and MAP).
4. Monitoring devices may be complex with many potential sources of error (e.g. ‘blocked’ catheters, failure to re-level the transducer after a change in the patient’s position). Readings should always be interpreted with care and in conjunction with clinical assessment.
5. Invasive monitoring has its own hazards (infection, trauma and immobility) and should be removed if no longer required.

Pulmonary Artery Catheterisation (see Chapter 24)

Although bedside echocardiography and other less invasive methods have superseded PA catheter use in some institutions, PA catheterisation remains a widely used method for measurement of LAP and PAP, and assessment of CO using a pulmonary thermodilution technique. Although generally viewed as the ‘gold standard’ for determining CO, the error is at least 10%, even with fastidious attention to technical detail.[61,62]

Inflation of the balloon at the end of the catheter provides a PA occlusion pressure (or pulmonary capillary wedge pressure), which reflects LAP provided there are no significant pulmonary vascular bed abnormalities, as occur in chronic obstructive pulmonary disease and long-standing mitral valve disease. Despite obtaining a good-quality wedge tracing, the measurement must be interpreted with caution since increased intrathoracic pressure and diastolic dysfunction make this pressure measurement an unreliable index of true LV volume preload.

The focus on ‘goal-directed therapy’ led to the widespread use of PA catheters, but their indiscriminate use was challenged by a multicentre case-controlled study, which suggested that patients managed with a PA catheter had a poorer outcome than those managed without such intervention.[63,64] This probably reflected the enthusiasm for inappropriate goal-directed therapy prevalent at that time, poor training in the use of the catheter and an inability of clinicians to respond appropriately to the data obtained.[65] More recent data is mixed, showing neither harm nor benefit with the use of a PA catheter.[66] However, with increasing use of MCS strategies, retrospective data exists suggesting a survival benefit if PA catheter-derived haemodynamically profiling is used prior to MCS in patients with CS. However, high-quality, prospective data are currently lacking.[51]

Box 33.4 lists the indications for PA catheterisation in heart failure.

Box 33.4

Indications for pulmonary arterial catheterisation in patients with heart failure

Failure to improve with initial circulatory management and uncertainty about adequacy of cardiac output and relationship between atrial filling pressures

Assessment of left ventricular preload when the relationship between right and left atrial pressures is uncertain owing to recent myocardial infarction, valvular abnormalities or high pulmonary vascular resistance. A low wedge pressure indicates that further volume is indicated, but a high value does not necessarily exclude the need for further volume

Measurement of cardiac output by thermodilution to direct appropriate choice of vasoactive drug and to manipulate therapy, particularly when high doses are being used

Need to monitor pulmonary arterial pressures and assess right ventricular function

Assessment of Intravascular Volume Status

Clinical

This is conventionally based on the measurement of the right atrial filling pressure and the assumption that a normal relationship exists between the atrial filling pressures, which is not necessarily valid in the critically ill patient, particularly in CS. Although values less than 8 mm Hg suggest hypovolaemia, higher levels are more difficult to interpret, particularly in the ventilated patient. The RAP should therefore be interpreted carefully and in light of other clinical evidence. However, such static tests for assessing the intravascular volume are less valuable than dynamic tests, such as the fluid challenge [67], [68] and the effect of positive-pressure ventilation, [69–72] which assess the circulatory response to an intervention. The central venous pressure (CVP), when used in conjunction with a fluid challenge, remains a useful metric to monitor as it may demonstrate RV intolerance to volume loading if RAP rises without an increase in CO, therefore acting as a 'stopping rule' rather than a numerical target to hit. [73]

Intravascular volume depletion is suggested if hypotension is precipitated by sedation, analgesia and postural change. In the patient receiving positive-pressure ventilation, respiratory fluctuation in the arterial pressure tracing (colloquially termed 'swing') also suggests relative hypovolaemia. This is confirmed if brief disconnection from the ventilator causes the blood pressure to rise and venous pressure to fall; the measurement off the ventilator more accurately reflects the ventricular end-diastolic transmural pressure. This manoeuvre is relatively contraindicated in patients with severe respiratory failure as loss of PEEP may cause widespread alveolar collapse.

Fluid Challenge

Hypovolaemia may be obvious in the setting of major blood loss or significant fluid shifts, however, in less clear cases the decision to administer a fluid bolus should be carefully considered so as to avoid the deleterious effects of volume overload. Predictors of fluid responsiveness exist to help the clinician determine whether a fluid bolus is likely to be beneficial; pulse pressure and stroke volume variation, IVC collapsibility and end expiratory occlusion testing have all been described for this purpose. [74]

If a fluid challenge is administered, the impact on blood pressure, flow and preload should be observed. In the volume-depleted patient, blood pressure and flow will increase with only a small, transient increase in filling pressure. While pulmonary gas exchange and overall fluid balance remain satisfactory, there is less anxiety about giving further fluid. Sufficient volume will have been given when either the target pressures are achieved and the evidence of poor peripheral perfusion and organ dysfunction has resolved, or when there is a sustained rise in filling pressures to a level above which there is a risk of pulmonary oedema developing. An objective assessment of the effect of such a fluid challenge can also be made by looking for a ≥10% rise in stroke volume. Caution is warranted with this approach; higher rates of critical care admission, requirement for organ support and increased mortality have been shown with as little as 1 L fluid administration administered early in the course of hospital admission for AHF, compared to diuretic treatment alone.[75]

If there is concern about administering a fluid challenge, an assessment of fluid responsiveness in critically ill patients can be made using a passive leg raising test[76],[77]; this results in a 'reversible' fluid challenge, as ~300 mL venous blood from the lower body is diverted towards the right heart.

Echocardiography (see Chapter 23)

Echocardiography is useful in identifying inadequate volume preload and the need for further fluid resuscitation, particularly when the preload pressures are high, as may occur with diastolic dysfunction. Performing serial studies to assess the response to therapy (fluid challenge, starting vasoactive therapy, changing ventilator settings) can be particularly valuable.

Management of Cardiac Function in the Critically Ill

Following initial assessment and with knowledge of the primary diagnosis, the need for extra monitoring should be decided, provisional targets should be set for fluid balance, central venous saturation ($ScvO_2$), mean and diastolic arterial pressures and a management plan agreed on how to achieve these goals. Generally, a MAP of 60–65 mm Hg with a diastolic pressure greater than 50 mm Hg is acceptable, but adequate cerebral, coronary, splanchnic and renal perfusion may require higher pressures, particularly in the elderly patient with pre-existing hypertension or widespread atheromatous disease.

Correction of Metabolic Factors

The following metabolic factors should be promptly corrected in most cases:

- *hypoxaemia:* PO_2 <8.0 kPa (< 60 mm Hg)
- *acidaemia:* pH <7.35
- *hyperkalaemia:* K^+ >5.5 mmol/L
- *hypomagnesaemia:* Mg^{2+} <0.9 mmol/L
- *hypocalcaemia:* ionised Ca^{2+} <1.0 mmol/L
- *hypophosphataemia:* PO_4^{3-} < 0.8 mmol/L
- *anaemia:* Hb <80 g/L
- *thiamine (vitamin B1) deficiency:* malnutrition, chronic alcohol use, diuretic or digoxin treatment.

A pH <7.35 and a negative base excess should be promptly corrected since myocardial contractility may be significantly reduced in the presence of a metabolic acidaemia. The suggestion that sodium bicarbonate should not be used as it produces a damaging paradoxical intracellular acidosis is misleading since the experiments demonstrating this effect were performed in vitro using non-physiological solutions, within a closed system that allowed no correction for any rise in carbon dioxide concentration and in which the sodium bicarbonate was given by bolus rather than by slow infusion.[78] The case for using bicarbonate to correct a metabolic acidaemia in the clinical setting has been recognised.[79]

In light of an ever-increasing evidence base, a restrictive transfusion policy has been adopted for the majority of critically ill patients, where a transfusion threshold of <70 g/L exists. However, a higher threshold is recommended in cardiac surgery (75 g/L) and for those with stable cardiovascular disease or acute coronary syndromes (80 g/L).[80–82]

Patients with poor dietary thiamine (vitamin B1) intake, chronic alcohol use and those on chronic furosemide or digoxin therapy are at risk of thiamine deficiency, resulting in impaired myocardial function, termed ‘wet beriberi’. Thiamine supplementation may improve LV function in these patients.[83, 84]

Selection of Appropriate Vasoactive Agents (see Chapter 26)

The choice of vasoactive agent when treating AHF represents a balance between the global requirements of the circulation and those of a stressed myocardium. The impact of these drugs in individual patients will be influenced by the baseline state of the circulation; that is, if either intensely constricted or dilated, the same drug will potentially produce different effects on pressure, flow and its distribution. The initial choice of vasoactive agent will depend on the MAP, CO and derived systemic vascular resistance (SVR). For example:

- *CO and MAP are both low with a high SVR:* an inotropic and dilating (inodilator) effect is required and dobutamine or milrinone would be appropriate. Levosimendan would also be a suitable choice in this setting. If CO rises but MAP falls, as may happen with dobutamine, milrinone and levosimendan and a more powerful inotropic effect is required, epinephrine may be appropriate. However, increasing doses of epinephrine risk myocardial ischaemia, ventricular irritability, splanchnic ischaemia and the development of hyperlactatemia. [85] Consequently, it is often more appropriate to use norepinephrine to maintain MAP when inodilating drugs are being administered.
- *MAP and SVR are low with high CO:* this is frequently seen in sepsis: arteriolar constriction with norepinephrine and/or vasopressin is indicated after adequate volume resuscitation.
- *MAP is at or above target, but CO is low with raised SVR:* a dilating agent (e.g. glyceryl trinitrate and nicardipine) or an inodilator is appropriate.

When PVR and RAP are acutely raised, a pulmonary vasodilator to offload the RV and maintain CO is required but hypotension may result from concomitant systemic arteriolar dilation and hypoxaemia can develop owing to increased ventilation–perfusion mismatch. Conversely, inhaled pulmonary vasodilators, such as nitric oxide, epoprostenol (a naturally occurring prostaglandin) or the synthetic prostaglandin analogue, iloprost, can improve V/Q matching and reduce PVR in well-ventilated regions of the lung but their use may be limited by side effects. [86], [87]

Dopamine has been widely used in the erroneous belief that it selectively improves renal blood flow. [88] A randomised controlled trial demonstrated a greater number of adverse events with the use of dopamine compared with norepinephrine in patients with shock. Moreover, in a predefined subgroup of patients with CS mortality was higher in patients treated with dopamine. [89]

Patients with CHF and those receiving beta-agonist infusions often develop tolerance with reduced catecholamine receptor responsiveness, resulting in less effect in raising intracellular cyclic adenosine monophosphate (cAMP) levels and increasing myocardial contractility. PDE-3 inhibitors (milrinone, enoximone) offer an alternative strategy independent of beta-receptor stimulation. There is also improvement in ventricular diastolic relaxation and a reduction in PVR. However, these agents are powerful vasodilators and hypotension frequently limits their use or requires a norepinephrine infusion to maintain SVR.

Levosimendan is an intracellular calcium sensitiser and thus bypasses the receptors through which other inotropic agents act. It binds to and sensitises cTnC to calcium without raising intracellular calcium, thus improving cardiac performance and contractility during systole without impairing ventricular relaxation during diastole. Administered as a continuous infusion for up to 24 hours, it has pharmacologically active metabolites which provide a prolonged duration of action with inotropic effects being sustained for several days. [90] Although, dose-dependent hypotension may occur due to action on adenosine triphosphate (ATP)-sensitive potassium channels, the reduction in preload and afterload and improved coronary blood flow will be beneficial to the failing heart. Furthermore, levosimendan also has inhibitory effects on PDE-3 contributing to its inodilator effects. [91] Levosimendan can also be used concomitantly with beta-blockers owing to its site of action, which does not involve beta-adrenergic receptors. [92] Its role in severe acute decompensated heart failure and CS following AMI appears promising, with a favourable safety profile in comparison to other inotropic agents.[93–95] Although there is a suggestion of a mortality benefit in adult cardiology and cardiac surgical patients, definitive randomised data is currently lacking.[96–99]

Beta-Blockade

Several studies have demonstrated a reduction in mortality and number of hospitalisations in patients with CHF treated with beta-blockers and their use is widely recommended in this setting.[9, 35] Furthermore, large studies have demonstrated their benefit early after AMI.[100]

Although beta-blockers are usually commenced in stable patients with heart failure, there is evidence that they may be safely initiated in patients recovering from recent decompensation, or in fact, continued at a reduced dose during an episode of decompensation.[101, 102] Indeed this is a complex issue as the potential detrimental effects, which include a mortality signal, of abrupt beta-blocker withdrawal should not be forgotten in those taking them long term for chronic cardiac disease.[103]

If tachycardia develops or persists during an episode of acute decompensated heart failure, it may be appropriate to consider a trial of a beta-blocker once the patient is stable, but it is advisable to start with a small dose of a short-acting drug, such as metoprolol or a low-dose esmolol infusion. If this beta-blocker ‘challenge’ is successful then the beneficial effects will include an increased time for ventricular filling, improved coronary perfusion and reduced myocardial oxygen demand.

Positive Pressure Ventilation

Continuous positive airway pressure (CPAP), non-invasive intermittent positive pressure ventilation (NIPPV) and invasive mechanical ventilation are commonly used to provide support for patients with acute cardiogenic pulmonary oedema. A systematic review concluded that non-invasive ventilation reduced hospital mortality, endotracheal intubation and ICU length of stay.[104] Benefits result from improved oxygenation, reduction of work of breathing and alleviation of myocardial ischaemia. The effects of positive pressure extend to augmenting stroke volume and CO via afterload reduction through lowering of LV transmural pressures. [105]

Anaesthetic agents given for intubation will reduce endogenous levels of catecholamines leading to potentially catastrophic hypotension. This should be anticipated, and vasoactive support considered peri-induction.

Mechanical Circulatory Support

Despite a paucity of supportive high-quality data, the use of short-term MCS has increased significantly. [15] Such devices may be employed in the setting of refractory CS in carefully selected patients to supplement CO and provide adequate end-organ perfusion.

Short-term MCS can be used as a bridge to recovery, bridge to decision (transplant or palliation) or as a bridge to a bridge and should be guided by an experienced CS-MDT in a specialist centre.

Due to the potential of significant complications (including bleeding, vascular injury, stroke and limb ischaemia), widespread adoption of these devices in unselected patients cannot yet be recommended in the absence of robust outcome data. [9]

The most common short-term MCS devices used include the intra-aortic balloon pump (IABP), the Impella microaxial support device and veno-arterial extracorporeal membrane oxygenation (VA-ECMO).

IABP counterpulsation is physiologically attractive as it reduces afterload, improves coronary and peripheral circulatory perfusion and decreases cardiac work. This results in a more efficient cardiac performance with improvement in both CO and myocardial oxygenation. [106] A common indication for IABP insertion is CS complicating AMI; however, randomised controlled trial data has questioned the benefit of the IABP in this setting; of note there was no significant difference in 30-day mortality between IABP and no IABP groups in one study. [107] Other indications for IABP support include weaning from cardiopulmonary bypass, high-risk percutaneous coronary intervention (PCI), although current evidence does not support the routine insertion of IABP in this setting, [108] and as a ‘bridging therapy’ to cardiac transplantation. The main absolute contraindications to IABP insertion are moderate-to-severe aortic regurgitation and aortic dissection, and complications include limb and bowel ischaemia, bleeding and infection.

The Impella devices are a group of intravascular, microaxial blood pumps which provide haemodynamic support in the setting of CS or high-risk PCI. The Impella 2.5 and Impella CP are percutaneously inserted in LV support devices providing flow of up to 2.5 L/min and 3.5 L/min respectively. The Impella 5.5 can provide up to 5 L/min of flow but requires surgical implantation. All devices augment systemic and coronary perfusion by pumping blood from the LV into the ascending aorta, thus offloading the heart and reducing myocardial work. A right-sided support device (Impella RP) is also available. [17]

While high-quality prospective data is lacking, a recent retrospective, registry-based cohort study compared microaxial flow devices and IABP in patients with CS complicating AMI; the use of intravascular microaxial support devices was associated with increased adjusted risk of death and major bleeding events. [109]

VA-ECMO can provide short-term circulatory support in refractory CS. In this circumstance, VA-ECMO will act as a bridge to myocardial recovery, to a ventricular assist device (VAD) or to heart transplantation. VA-ECMO is also used peri-operatively in cardiac surgery and during cardiopulmonary arrest (termed E-CPR). [110] A recently published multicentre randomised trial, and subsequent meta-analysis, failed to demonstrate a mortality benefit utilising VA-ECMO early in AMI-CS as compared with standard care; VA-ECMO was also associated with higher complication rates in this group. [111], [112]

VADs are mechanical systems that provide circulatory support for patients with severe AHF and CHF. Support can be provided for the LV, the RV or both. VADs are currently used in AHF refractory to standard therapies as a bridge to myocardial recovery or heart transplantation. However, depending on the healthcare system, these devices can be used as a ‘destination therapy’ in patients with end-stage CHF who are not eligible for heart transplantation; mean survival after implantation is approaching 5 years. [113], [114] Complications associated with VADs can be significant and include device failure, bleeding, infection, thromboembolism and stroke.

Cardiogenic Shock After Acute Myocardial Infarction

The incidence of CS has remained relatively unchanged over recent years, occurring in up to 10% of patients following acute myocardial infarction (AMI-CS), and despite aggressive intervention strategies the mortality rate remains significant in patients in whom shock is present (~50%). [115] In patients admitted to critical care with AMI-CS, the following additional points should be noted:

- The effects of management on myocardial oxygenation must be considered as well as global circulatory targets.
- Although the patient may be ventilated in the ICU, therapies demonstrated to improve myocardial salvage must not be overlooked or delayed. Emphasis should be placed on early revascularisation therapy, and patients should undergo urgent coronary angiography to allow PCI if appropriate. A recent multicentre study demonstrated a lower risk of death or severe renal failure in patients who had multivessel disease and AMI-CS, but underwent PCI of the culprit lesion only. [116] The benefits of aspirin are significant if given in the early hours after infarction; if necessary the aspirin can be given rectally. A beta-blocker and an ACE inhibitor should be started as soon as clinically possible but bradycardia, heart block, persisting shock and the presence of impaired renal function may cause delay in initiating treatment. Once stable, patients with LV dysfunction and heart failure should also be started on an aldosterone receptor antagonist e.g. eplerenone. Recent studies have shown a benefit of sodium-glucose cotransporter 2 inhibitors (dapagliflozin or empagliflozin) in patients with symptomatic CHF irrespective of the presence of diabetes, reducing the composite of death or HF-related hospitalisation by 25%. [117], [118] Most recently, semaglutide, a glucagon-like peptide 1 receptor agonist approved for long-term weight management, has been shown to improve heart failure-

related symptoms, exercise tolerance and weight loss in patients with HFpEF and obesity. [119]

- In patients admitted following an out-of-hospital cardiorespiratory arrest, the optimal targeted temperature management (TTM) has been the subject of several trials. [120–123] There is currently insufficient evidence to recommend routine cooling to 32–36°C, however, active fever prevention is advocated for 72 hours post-cardiac arrest in comatose patients in European guidelines. TTM should not prevent other interventions, such as primary PCI being performed if appropriate.
- It is also important to recognise:
  - RV infarction (ST elevation in lead V_3R and/or V_4R in patients with inferior ST-segment elevation MI is highly specific for RV ischaemia due to a proximal right coronary artery occlusion) since further monitoring may be necessary to ensure appropriate volume loading and right heart directed therapies.
  - the development of either a ventricular septal defect or mitral regurgitation from papillary rupture as urgent surgery may be indicated. [124]

Pulmonary Hypertension

Pulmonary hypertension (PH) is a major global health concern and is a frequently encountered pathophysiological disorder in ICU associated with a high mortality. [125] Box 33.5 summarises the most recent clinical classification of PH. [126] The classification splits PH into five diagnostic groups according to underlying cause. An important distinction to note is that group 1 PH or pulmonary arterial hypertension (PAH), previously known as primary PH, includes a set of disorders where PH is the primary problem. In contrast, all other classification groups are due to conditions that lead to PH as a result of cardiac dysfunction, abnormalities in the lung parenchyma, chest wall abnormalities or mechanical obstruction of the pulmonary vasculature.

Box 33.5

Clinical classification of pulmonary hypertension

GROUP 1 Pulmonary arterial hypertension (PAH)

- 1.1 Idiopathic
    - 1.1.1. Non-responders at vasoreactivity testing
    - 1.1.2. Acute responders at vasoreactivity testing
- 1.2 Heritable [a]
- 1.3 Associated with drugs and toxins [a]
- 1.4 Associated with:
    - 1.4.1. Connective tissue disease
    - 1.4.2. HIV infection
    - 1.4.3. Portal hypertension
    - 1.4.9. Congenital heart disease
    - 1.4.5. Schistosomiasis
- 1.5 PAH with features of venous/capillary (PVOD/PCH) involvement
- 1.6 Persistent PH of the newborn

GROUP 2 PH associated with left heart disease

- 2.1 Heart failure
    - 2.1.1. with preserved ejection fraction
    - 2.1.2. with reduced or mildly reduced ejection fraction [b]
- 2.2 Valvular heart disease
- 2.3 Congenital/acquired cardiovascular conditions leading to post-capillary PH

GROUP 3 PH associated with lung diseases and/or hypoxia

- 3.1 Obstructive lung disease or emphysema
- 3.2 Restrictive lung disease
- 3.3 Lung disease with mixed restrictive/obstructive pattern
- 3.4 Hypoventilation syndromes
- 3.5 Hypoxia without lung disease (e.g. high altitude)

- 3.6 Developmental lung disorders

GROUP 4 PH associated with pulmonary artery obstructions

- 4.1 Chronic thrombo-embolic PH
- 4.2 Other pulmonary artery obstructions [c]

GROUP 5 PH with unclear and/or multifactorial mechanisms

- 5.1 Haematological disorders [d]
- 5.2 Systemic disorders [e]
- 5.3 Metabolic disorders [f]
- 5.9 Chronic renal failure with or without haemodialysis
- 5.5 Pulmonary tumour thrombotic microangiopathy
- 5.6 Fibrosing mediastinitis

[a] Patients with heritable PAH or PAH associated with drugs and toxins might be acute responders.

[b] Left ventricular ejection fraction for HF with reduced ejection fraction: ≤40%; for HF with mildly reduced ejection fraction: 41%–49%.

[c] Other causes of pulmonary artery obstructions include sarcomas (high or intermediate grade or angiosarcoma), other malignant tumours (e.g. renal carcinoma, uterine carcinoma, germ-cell tumours of the testis), non-malignant tumours (e.g. uterine leiomyoma), arteritis without connective tissue disease, congenital pulmonary arterial stenoses, and hydatidosis.

[d] Including inherited and acquired chronic haemolytic anaemia and chronic myeloproliferative disorders.

[e] Including sarcoidosis, pulmonary Langerhans's cell histiocytosis and neurofibromatosis type 1.

[f] Including glycogen storage diseases and Gaucher disease.

HF , Heart failure; *HIV* , human immunodeficiency virus; *PAH* , pulmonary arterial hypertension; *PCH* , pulmonary capillary haemangiomatosis; *PH* , pulmonary hypertension; *PVOD* , pulmonary veno-occlusive disease.

From Humbert M, Kovacs G, Hoeper MM, et al. 2022 ESC/ERS Guidelines for the diagnosis and treatment of pulmonary hypertension. *Eur Heart J* . 2022;43(38):3618-3731. doi:10.1093/eurheartj/ehac237. Published correction appears in *Eur Heart J* . 2023;44(15):1312.

The definition of PH has recently changed to reflect contemporary data and facilitate early disease detection. PH is defined as a mean pulmonary arterial pressure (mPAP) greater than or equal to 20 mm Hg on right heart catheterisation while the patient is at rest. [126] This is the mPAP above which there is a significant increase in mortality and hospitalisation rate. Pulmonary artery wedge pressure and pulmonary vascular resistance (PVR) measurements are also incorporated in the definition of PH in order to distinguish the various haemodynamic subgroups (Box 33.6).

Box 33.6

Pulmonary hypertension: Haemodynamic subgroups

Definition	Haemodynamic characteristics
PH	mPAP >20 mm Hg
Pre-capillary PH	mPAP >20 mm Hg PAWP ≤15 mm Hg PVR >2 WU
IpcPH	mPAP >20 mm Hg PAWP >15 mm Hg PVR ≤2 WU
CpcPH	mPAP >20 mm Hg PAWP >15 mm Hg PVR >2 WU
Exercise PH	mPAP/CO slope between rest and exercise >3 mm Hg/L/min

Some patients present with elevated mPAP (>20 mm Hg) but low PVR (≤2 WU) and low PAWP (≤15 mm Hg).

CO , cardiac output; *CpcPH* , combined post- and pre-capillary pulmonary hypertension; *IpcPH* , isolated post-capillary pulmonary hypertension; *mPAP* , mean pulmonary arterial pressure; *PAWP* , pulmonary arterial wedge pressure; *PH* , pulmonary hypertension; *PVR* , pulmonary vascular resistance; *WU* , Wood units.

In the critical care setting, common pathological conditions leading to PH include severe respiratory failure; acute respiratory distress syndrome (ARDS); left-sided heart failure leading to increased LAP; massive PE;

mechanical ventilation; and following cardiac and thoracic surgery. The presence of PH in many of these conditions is associated with increased mortality. In addition, several factors including sepsis, cardiac arrhythmias and treatment failure can precipitate acute exacerbations of chronic PAH leading to ICU admissions. Sepsis in these patients is associated with a poor outcome. [127] The development of severe right heart failure in this patient group carries with it a high mortality and specialist centres should be involved at an early stage. Any potentially reversible causes of decompensation such as infection or arrhythmias should be sought and treated. Right heart catheterisation should be considered and pulmonary arterial hypertensive medications explored on an individual basis. A small subset of patients may be candidates for mechanical RV support as a bridge to recovery or transplantation. [126]

Pathophysiology

An understanding of the pathophysiological changes seen in patients with PH is essential to understand the available treatment strategies and the likelihood of their success. Invariably the most crucial manifestation of PH is RV dysfunction. Under normal conditions RV outflow is to a high-compliance, low-pressure and low-resistance system. The thin-walled RV is highly sensitive to small increases in the PVR leading to ventricular dilation, an increase in end-systolic volume and reduced RV ejection fraction and pulmonary blood flow. This in turn results in a reduction in CO. In the initial stages the RV responds by enhancing contractility in order to maintain CO. [128] Further increases in RV afterload overwhelm these compensatory mechanisms resulting in reduced CO and systemic circulatory failure. The intimate anatomical relationship of the two ventricles sharing a septum and both being bound by tight pericardial fibres results in ventricular interdependence. In the setting of increased afterload the dilated RV loses its normal shape and pushes the septum towards the LV, thereby compromising LV filling and output. RV dilation can also lead to tricuspid regurgitation further lowering CO. In addition to these anatomical considerations, a fall in systemic blood pressure can compromise RV coronary perfusion, thereby leading to ischaemia and further RV dysfunction. Unlike the LV, under normal conditions, coronary perfusion to the RV is maintained throughout the cardiac cycle. As RV pressure increases there is a decrease in the perfusion pressure gradient between the aorta and the RV during systole, thereby limiting coronary perfusion mainly to diastole.

The impact of impaired RV function on venous congestion should not be ignored; elevated systemic venous pressure has the potential to impair the perfusion of all organs. Clinically this is often manifest by progressive renal, liver and gut dysfunction. Inappropriate fluid administration may cause further venous congestion and organ impairment. In later stages, bowel wall oedema occurs, altering its permeability leading to bacterial and toxin translocation with a subsequent sepsis-like inflammatory response.[129]

Acute Cor Pulmonale

Acute cor pulmonale (ACP) is caused by acute pressure overload of the RV due to an acute increase in PVR and thus RV afterload. The RV dilates acutely, RV systolic function is impaired and the interventricular septum becomes dyskinetic and displays paradoxical motion.[130,131] ACP is commonly seen in critically ill patients with severe ARDS and following massive PE. The incidence of ACP in severe ARDS was historically reported to be 50%–60%; however, this has been reduced to 20%–30% following the widespread adoption of lung protective ventilation strategies.[132] The detection of ACP is independently associated with increased mortality in patients with severe ARDS and will ultimately result in acute circulatory failure if it is not managed aggressively.

Clinical Aspects

Key to the management of patients with PH is diagnosis of the underlying cause and, if feasible, treatment should focus on prompt reversal of precipitating factors such as infection, arrhythmias, anaemia and pulmonary emboli. Principles of management include optimising fluid balance (RV preload), reducing RV afterload, maintaining perfusion pressures and improving RV contractility.[132,133] The prone position, as a means to offload the RV, can also be considered.[134] Like most other disorders requiring critical care, the maxim of good ICU care is also applicable to these patients. The discussion that follows looks at treatment strategies specific to PH and the associated RV dysfunction.

Monitoring

The gold standard for diagnosing and monitoring PH in the ICU remains the PA catheter. Echocardiography is increasingly being used and can provide clinicians with much of the information needed to manage such patients. A recent systematic review and meta-analysis found that although echocardiography was of clinical value in diagnosing PH, right heart catheterisation remains the gold standard.[135] The virtues of echocardiography in PH in ICU populations have not been studied, and ultimately available expertise is likely to dictate local practice.

If RV failure is suspected or confirmed then a central venous catheter is mandatory to allow CVP and $ScvO_2$ monitoring, as well as administration of vasoactive medications if required.

Management

The need for adequate oxygenation applies to most critically ill patients but assumes greater importance in PH. RV myocardial oxygen demands are increased in severe PH and hypoxia may increase PVR by exacerbating hypoxic pulmonary vasoconstriction. In many cases, mechanical ventilation may be unavoidable; however, it comes at a cost. Positive-pressure ventilation has adverse effects on RV afterload and along with administration of sedatives can further compromise CO. Ventilatory strategies should focus on maintaining adequate oxygenation while avoiding high plateau pressures.

Fluid resuscitation of patients with PH is extremely challenging. A normally functioning RV is usually preload dependent. However, in RV failure, even in the setting of low CO and shock, the decision to give IV fluid should be carefully considered. A significant proportion of these patients will have grossly elevated filling pressures, and it is unusual for this group of patients to be fluid deplete. RV dilation as a consequence of volume overload can lead to impaired RV function and impaired LV filling, due to ventricular interdependence, which results in a reduction in systemic CO. In patients with evidence of RV volume overload and septal bowing, aggressive fluid removal, with diuretics or renal replacement therapy, should be considered as it may improve CO as a consequence of improved LV filling and may serve to decongest organs faced with elevated venous pressure. Trending a CVP may help to guide fluid therapy in this particular instance by allowing early detection of volume intolerance.

The maintenance of sinus rhythm in these patients will improve RV end-diastolic volume and CO. Where possible, cardioversion should be performed in patients with tachyarrhythmias. In those patients where this cannot be achieved, the focus should be on rate control to optimise ventricular filling time.

Vasopressors and inotropes

The goal of using vasoactive drugs in patients with RV dysfunction secondary to PH is to maintain an adequate CO while avoiding increases in PVR and cardiac arrhythmias. In the face of systemic hypotension norepinephrine or vasopressin, both systemic vasoconstrictors, should be considered in these patients. Improving systemic blood pressure has the benefit of improving RV, in addition to LV, coronary perfusion. It should be noted that at higher doses norepinephrine causes pulmonary vasoconstriction whereas vasopressin causes pulmonary vasodilation and therefore may be more beneficial in PH. [136]

High-quality trial data regarding inotropic support in this setting is lacking. Evidence from animal studies suggests that low-dose dobutamine may be useful in acute PH complicated by RV failure. [137] However, increases in myocardial oxygen demand and tachyarrhythmias may preclude dobutamine use in all patients with PH. In another animal study, the use of levosimendan and dobutamine in PH was compared. Improvement in RV contractility was similar after administration of both drugs; of the two agents, levosimendan was superior at reducing PVR. [138] Small observational studies in humans have shown a similar trend of improved RV contractility and reduced PVR following the administration of levosimendan in patients with CS.[139] In theory, levosimendan appears to be a promising alternative to dobutamine with the additional benefit of PVR reduction without increasing oxygen consumption.

PDE-3 inhibitors, such as milrinone, have inotropic and vasodilating properties. They can improve CO by reducing PVR and increasing RV contractility. PDE-3 inhibitors have been shown to successfully reduce PVR and improve RV contractility in animal models of PH[140], [141] and in patients undergoing cardiac surgery.[142], [143] However, treatment with milrinone may require additional vasopressor support, given its propensity for systemic vasodilation.

Digoxin is a cardiac glycoside with inotropic properties mediated via sodium-potassium ATPase pump inhibition, as well as having vagomimetic effects on the atrioventricular node.[144] Despite theoretical advantages in RH failure, a recent meta-analysis has failed to demonstrate benefit with regards to exercise capacity, RV ejection fraction or functional classification in this group.[145] Nevertheless, it may have a role in the treatment of atrial tachyarrhythmias in those with PAH.

Pulmonary Hypertension: Specific Therapies

In the subset of patients with known PAH admitted to the intensive care unit, usual disease-specific medications should be continued, unless advised otherwise by a specialist centre. Sudden cessation may precipitate sudden and profound decompensation.

The use of PAH-specific medications in the critically ill population is largely based on physiological rationale owing to the paucity of data in this group. An appreciation of the underlying cause of PH is essential, as the use of PAH-specific medications in non-Group 1 patients may be associated with worse outcomes.[146]

Inhaled nitric oxide (iNO) increases the production of cyclic guanosine monophosphate (cGMP) and is a potent pulmonary vasodilator. It results in the reversal of hypoxic pulmonary vasoconstriction, reduction in PVR and improved oxygenation. iNO therapy has been shown to reduce PVR and improve RV stroke work following heart transplantation and in postoperative cardiothoracic patients with PH.[147, 148] When used in the context of severe ARDS and hypoxaemia refractory to maximal medical treatment, iNO commonly provides 48 hours of improvement in oxygenation, but fails to reduce the length of mechanical ventilation or improve mortality.[149, 150] Methaemoglobinaemia and nitrogen dioxide (NO_2) production are recognised adverse effects and rebound PH may also occur after abrupt cessation of iNO. Cost limits its widespread use.

Epoprostenol is often the pulmonary vasodilator of choice for patients with PH and RV failure in the ICU owing to its titratability and short half-life. Benefit is suggested by a reduction in mPAP and an improvement in CO. Side effects include systemic hypotension and tachycardia. A continuous inhaled infusion may also be used; although this avoids systemic hypotension, it is less potent as a pulmonary vasodilator via this route. Inhaled iloprost, a synthetic prostacyclin analogue, has been shown to reduce mPAP and improve RV function in PH post-cardiopulmonary bypass and significantly reduces PVR to SVR ratio.[151] Inhaled prostacyclin showed similar efficacy to iNO in managing PH in both ICU patients and heart-lung transplant recipients.[86, 152] Trepostinil, also a prostacyclin analogue, has a role in long-term management of PAH, but may rarely be encountered in an ICU setting.[153]

Phosphodiesterase-5 (PDE-5) inhibitors (sildenafil, tadalafil) stop the degradation of cGMP in vascular smooth muscle leading to vasodilation. Sildenafil is a useful drug in the ICU setting owing to its short half life, favourable side-effect profile and availability in both oral and intravenous forms. In patients with PAH, oral sildenafil has been shown to reduce mPAP[154] and improve CO by reducing PVR.[155] Sildenafil has also been used as a bridge to avoid rebound hypotension following iNO withdrawal in post-cardiac-surgery patients.[156] Following haemodynamic stabilisation, there may be a role for sildenafil in reducing PVR in the critical care setting.

Endothelin receptor antagonists (bosentan, macitentan) block the vasoconstrictive effects of endothelin. They are used predominantly in an outpatient setting although they may have a limited role in critically ill patients. Owing to their teratogenic effects they should be avoided in pregnancy.[157, 158]

Mechanical devices

The decision to embark upon extracorporeal life support (ECLS) in this group of patients should be made in conjunction with specialist centres as it may be futile in patients without bridging options. Many forms of mechanical support are available, but peripheral VA-ECMO is the most commonly used. The use of MCS as a bridge to transplantation is becoming increasingly common in patients where all other treatment options have been exhausted. ECLS has also been described as a bridge to recovery in a small number of cases where a reversible cause has been identified.[129] VA-ECMO will help to unload the RV, reduce RV afterload and improve perfusion of vital organs and thus may provide temporary support in the acute situation.

Summary

PH and consequent RV dysfunction are frequently encountered in the ICU with a high associated mortality rate. Prompt identification of the underlying cause and its treatment should be the main focus of management. There is very little evidence for the use of specific treatments in the ICU setting and a ‘one-size fits all’ approach is unlikely to work given the varied aetiology. Specialist centres should be involved in management at any early stage. A few general principles, such as optimising fluid status, optimising HR and rhythm, avoiding high-pressure ventilation, maintaining coronary perfusion by optimising systemic pressure, inotropic support for RV dysfunction and inhaled pulmonary vasodilation may be applied where appropriate. The choice of individual therapies should be guided by an understanding of their mechanism of action and the expected physiological response in an individual patient. The response should be monitored closely to avoid adverse events and to optimise therapy.

Valvular and congenital heart disease and infective endocarditis

Steven Galluccio and Lisa-Marie Pereira

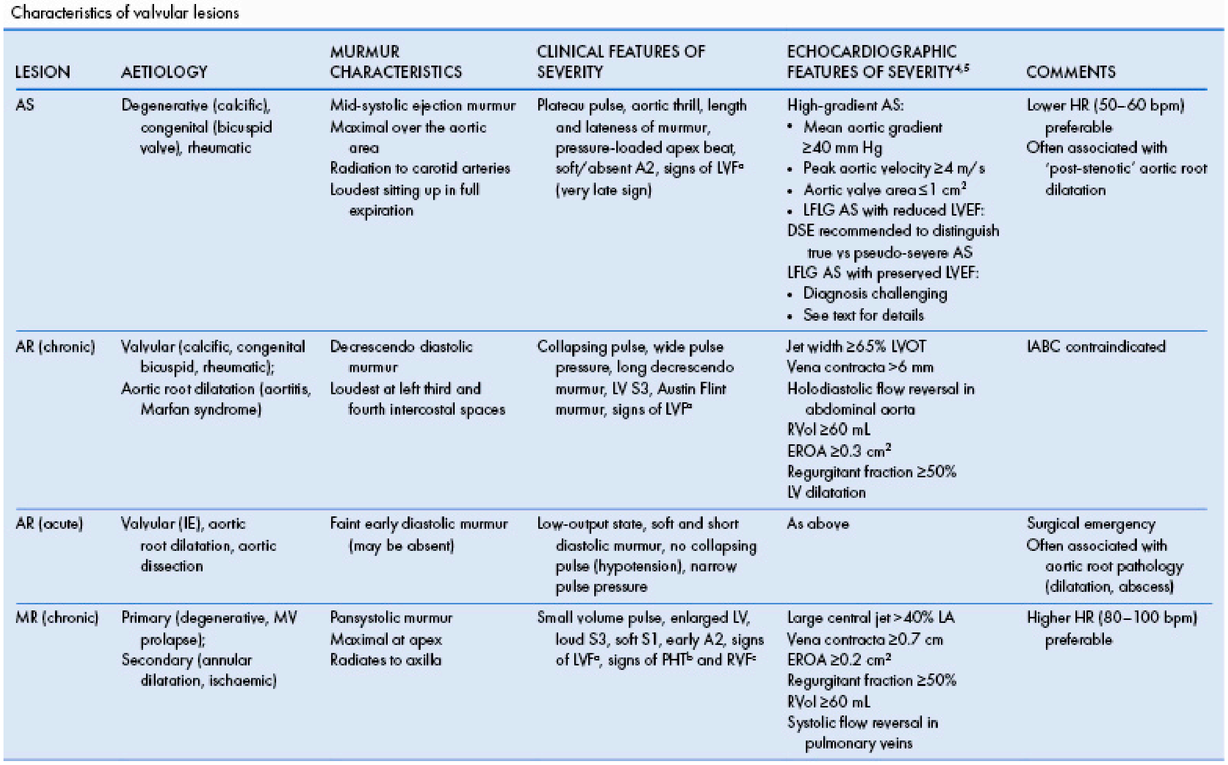
Valvular Heart Disease

Valvular heart disease (VHD) has been described as the next ‘cardiac epidemic’. [1] A variety of factors are driving the increasing global burden of VHD. In high-income and industrialised countries, the prevalence of aortic stenosis (AS) is increasing in association with an ageing population, whilst access to diagnostic and therapeutic options inflates. [2]

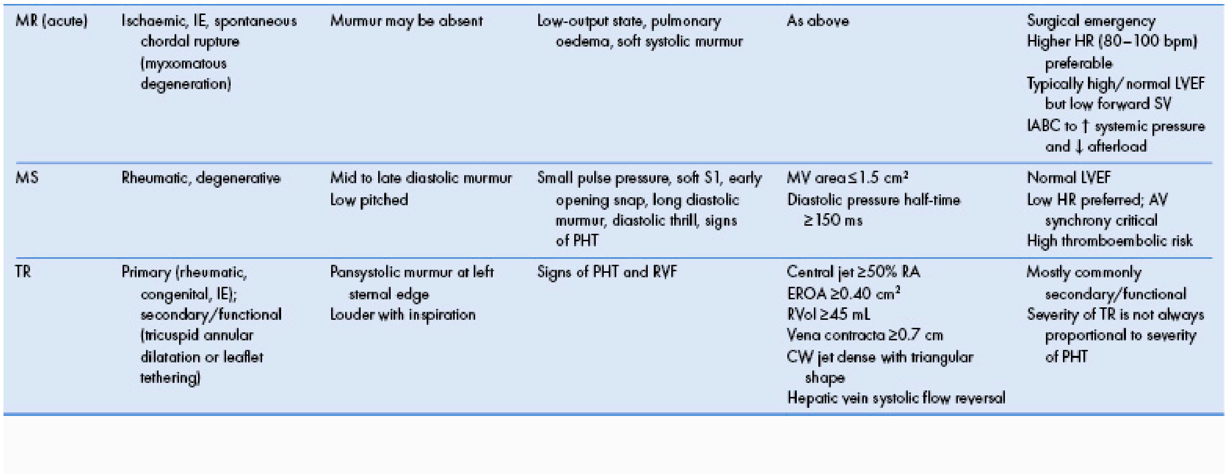
Contrastingly, rheumatic heart disease remains a significant entity in low-income countries or within low-income populations within high-income countries. [3]

For the intensivist, VHD may pose a clinical challenge as the primary cause for haemodynamic decompensation, when manifest with an unrelated concurrent illness, or in the peri-operative period where valve replacement or repair is performed. Haemodynamic support of severe uncorrected VHD in the critical care setting can be difficult since cardiac output may remain largely independent of conventional manipulations. Nonetheless, framing the underlying lesion and haemodynamic state into a conceptual model may help anticipate problems and predict responses to intervention (Tables 34.1 and 34.2).

Table 34.1



Characteristics of valvular lesions



LESION	AETIOLOGY	MURMUR CHARACTERISTICS	CLINICAL FEATURES OF SEVERITY	ECHOCARDIOGRAPHIC FEATURES OF SEVERITY[4,5]	COMMENTS
AS	Degenerative (calcific), congenital (bicuspid valve), rheumatic	Mid-systolic ejection murmur Maximal over the aortic area Radiation to carotid arteries Loudest sitting up in full expiration	Plateau pulse, aortic thrill, length and lateness of murmur, pressure-loaded apex beat, soft/absent A2, signs of LVF[a] (very late sign)	High-gradient AS: • Mean aortic gradient ≥40 mm Hg • Peak aortic velocity ≥4 m/s • Aortic valve area ≤1 cm^2 • LFLG AS with reduced LVEF: DSE recommended to distinguish true vs pseudo-severe AS LFLG AS with preserved LVEF: • Diagnosis challenging • See text for details	Lower HR (50–60 bpm) preferable Often associated with 'post-stenotic' aortic root dilatation
AR (chronic)	Valvular (calcific, congenital bicuspid, rheumatic); Aortic root dilatation (aortitis, Marfan syndrome)	Decrescendo diastolic murmur Loudest at left third and fourth intercostal spaces	Collapsing pulse, wide pulse pressure, long decrescendo murmur, LV S3, Austin Flint murmur, signs of LVF[a]	Jet width ≥65% LVOT Vena contracta >6 mm Holodiastolic flow reversal in abdominal aorta RVol ≥60 mL EROA ≥0.3 cm^2 Regurgitant fraction ≥50% LV dilatation	IABC contraindicated
AR (acute)	Valvular (IE), aortic root dilatation, aortic dissection	Faint early diastolic murmur (may be absent)	Low-output state, soft and short diastolic murmur, no collapsing pulse (hypotension), narrow pulse pressure	As above	Surgical emergency Often associated with aortic root pathology (dilatation, abscess)
MR (chronic)	Primary (degenerative, MV prolapse); Secondary (annular dilatation, ischaemic)	Pansystolic murmur Maximal at apex Radiates to axilla	Small volume pulse, enlarged LV, loud S3, soft S1, early A2, signs of LVF[a], signs of PHT[b] and RVF[c]	Large central jet >40% LA Vena contracta ≥0.7 cm EROA ≥0.2 cm^2 Regurgitant fraction ≥50% RVol ≥60 mL Systolic flow reversal in pulmonary veins	Higher HR (80–100 bpm) preferable
MR (acute)	Ischaemic, IE, spontaneous chordal rupture (myxomatous degeneration)	Murmur may be absent	Low-output state, pulmonary oedema, soft systolic murmur	As above	Surgical emergency Higher HR (80–100 bpm) preferable Typically high/normal LVEF but low forward SV IABC to ↑ systemic pressure and ↓ afterload
MS	Rheumatic, degenerative	Mid to late diastolic murmur Low pitched	Small pulse pressure, soft S1, early opening snap, long diastolic murmur, diastolic thrill, signs of PHT	MV area ≤1.5 cm^2 Diastolic pressure half-time ≥150 ms	Normal LVEF Low HR preferred; AV synchrony critical High thromboembolic risk
TR	Primary (rheumatic, congenital, IE); secondary/functional (tricuspid annular dilatation or leaflet tethering)	Pansystolic murmur at left sternal edge Louder with inspiration	Signs of PHT and RVF	Central jet ≥50% RA EROA ≥0.40 cm^2 RVol ≥45 mL Vena contracta ≥0.7 cm CW jet dense with triangular shape Hepatic vein systolic flow reversal	Mostly commonly secondary/functional Severity of TR is not always proportional to severity of PHT

---

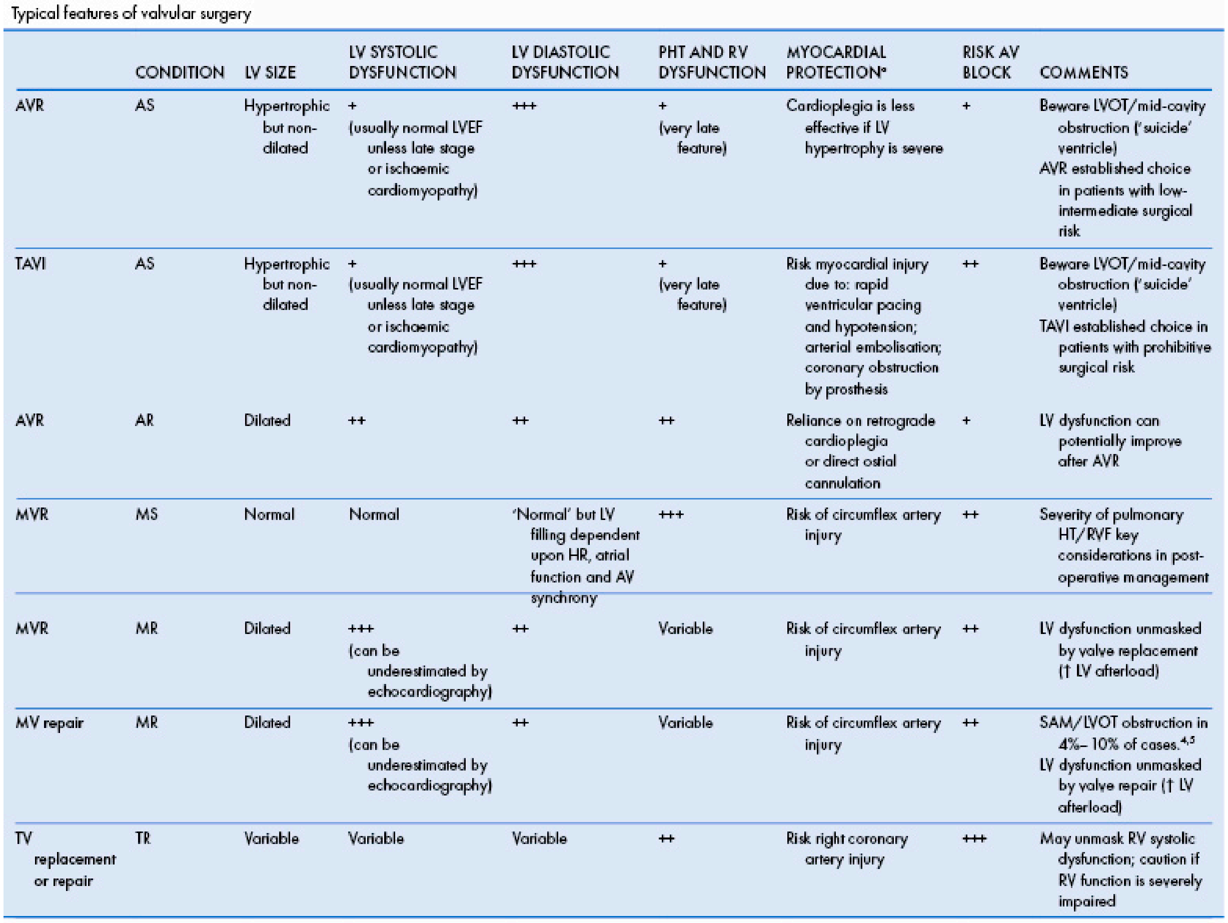
[a] Signs of LVF: tachypnoea, Cheyne-Stokes respiration, hypotension, low pulse pressure, LV S3, basal inspiratory crackles.

[b] Signs of PHT: loud P2, palpable P2, prominent A wave in JVP, left parasternal heave, RV S4.

[c] Clinical features of RVF: TR murmur, PR murmur, elevated JVP, prominent V wave in JVP, RV S3, hepatomegaly, pulsatile liver, peripheral oedema, ascites, pleural effusions.

AR , Aortic regurgitation; *AS* , aortic stenosis; *AV* , aortic valve; *EROA* , effective regurgitant orifice area; *HR* , heart rate; *IABC* , intra-aortic balloon counterpulsation; *IE* , infective endocarditis; *LFLG,* low-flow, low-gradient; *LV* , left ventricle; *LVEF* , left ventricular ejection fraction; *LVF* , left ventricular failure; *LVOT* , left ventricular outflow tract obstruction; *MR* , mitral regurgitation; *MS* , mitral stenosis; *MV* , mitral valve; *PHT* , pulmonary hypertension; *RV* , right ventricle; *RVF* , right ventricular failure; *RVol* , regurgitant volume; *SV* , stroke volume; *TR* , tricuspid regurgitation.

Table 34.2



Typical features of valvular surgery

	CONDITION	LV SIZE	LV SYSTOLIC DYSFUNCTION	LV DIASTOLIC DYSFUNCTION	PHT AND RV DYSFUNCTION	MYOCARDIAL PROTECTION[a]	RISK AV BLOCK	COMMENTS
AVR	AS	Hypertrophic but non-dilated	+ (usually normal LVEF unless late stage or ischaemic cardiomyopathy)	+++	+ (very late feature)	Cardioplegia is less effective if LV hypertrophy is severe	+	Beware LVOT/mid-cavity obstruction ('suicide' ventricle) AVR established choice in patients with low-intermediate surgical risk
TAVI	AS	Hypertrophic but non-dilated	+ (usually normal LVEF unless late stage or ischaemic cardiomyopathy)	+++	+ (very late feature)	Risk myocardial injury due to: rapid ventricular pacing and hypotension; arterial embolisation; coronary obstruction by prosthesis	++	Beware LVOT/mid-cavity obstruction ('suicide' ventricle) TAVI established choice in patients with prohibitive surgical risk
AVR	AR	Dilated	++	++	++	Reliance on retrograde cardioplegia or direct ostial cannulation	+	LV dysfunction can potentially improve after AVR
MVR	MS	Normal	Normal	'Normal' but LV filling dependent upon HR, atrial function and AV synchrony	+++	Risk of circumflex artery injury	++	Severity of pulmonary HT/RVF key considerations in post-operative management
MVR	MR	Dilated	+++ (can be underestimated by echocardiography)	++	Variable	Risk of circumflex artery injury	++	LV dysfunction unmasked by valve replacement († LV afterload)
MV repair	MR	Dilated	+++ (can be underestimated by echocardiography)	++	Variable	Risk of circumflex artery injury	++	SAM/LVOT obstruction in 4%– 10% of cases.[4,5] LV dysfunction unmasked by valve repair († LV afterload)
TV replacement or repair	TR	Variable	Variable	Variable	++	Risk right coronary artery injury	+++	May unmask RV systolic dysfunction; caution if RV function is severely impaired

[a] RV protection is worse when retrograde cardioplegia is solely used.

AR , Aortic regurgitation; *AS* , aortic stenosis; *AV* , aortic valve; *AVR* , AV replacement; *HT* , hypertension; *LV* , left ventricle; *LVEF* , left ventricular ejection fraction; *LVOT* , left ventricular outflow tract obstruction; *MR* , mitral regurgitation; *MS* , mitral stenosis; *MV* , mitral valve; *MVR* , MV replacement; *PHT* , pulmonary hypertension; *RV* , right ventricle; *RVF* , right ventricular failure; *SAM* , systolic anterior motion of the mitral valve; *TAVI* , transcatheter aortic valve implantation; *TR* , tricuspid regurgitation; *TV* , tricuspid valve.

Consensus guidelines provide recommendations for the timing of intervention for VHD. [6] , [7] The principles of decision making involve assessment of patient symptoms; echocardiographic determination of severity by standard criteria [8–10] ; presence of associated cardiac disease (e.g. coronary artery disease); co-morbidities and the risk of intervention utilising validated scoring systems.

Aortic stenosis

Left ventricular (LV) hypertrophy is the adaptive response to the pressure work brought about by AS. The initial pathophysiological hallmark is diastolic dysfunction, but as the disease progresses, dilatation ensues and overt systolic failure becomes evident. Typically, patients remain asymptomatic for a prolonged period, but once symptoms occur the prognosis is poor if left untreated.

Medical Management

For patients presenting with critical symptomatic AS, surgical or percutaneous intervention is required as medical management is limited. A modest heart rate is ideal and inotropic support may have a role if there is LV systolic dysfunction, but stroke volume is otherwise largely fixed. Vasodilators potentially have a temporising role but more critical is the defence of systemic pressure with vasopressors. Hypotension is an ominous sign and restoration of coronary perfusion pressure is paramount. This may require the addition of intra-aortic balloon counterpulsation (IABC).

Intervention for Aortic Stenosis

Aortic valve replacement (AVR) is recommended as a Class 1 indication for severe AS with symptoms, or when it is associated with decreased left ventricular ejection fraction (LVEF) or the need for other cardiac surgery. [6]

Determining the severity of AS

The classic echocardiographic hallmarks of severe AS are visibly reduced leaflet excursion coupled with a high peak transvalvular velocity gradient (>4 m/s). However, delineating severe AS is not always straightforward and may confound the intensive care physician at the bedside. Up to 50% of patients with truly severe AS do not exhibit such high peak or mean velocity gradients: these gradients are dependent not just upon the effective valve area but also on the *flow rate* across the valve (stroke volume per unit time). ‘Low-gradient AS’ can be associated with ‘classical low-flow’ states attributable to poor systolic function. In this scenario, augmentation of flow rate with dobutamine during echocardiography can differentiate truly severe AS (flow rate and gradients increase whilst calculated valve area by continuity equation remains fixed) from ‘pseudo’ severe AS (augmented systolic function and increased flow rates materially increase the effective valve area). Conversely, failure of dobutamine augmentation heralds a group with less favourable prognosis, with poor contractile reserve either due to intrinsic cardiomyopathy or afterload mismatch attributable to the AS alone. Predicting the outcome of this cohort with intervention remains uncertain; prognosis may still be improved with intervention versus conservative therapy. Finally, low-gradient AS can be ‘paradoxical’ whereby systolic function is preserved but the flow rate is reduced, usually due to restrictive physiology incorporating systemic hypertension, concentric LV hypertrophy and small chamber volumes. Determining the severity of AS in this group can be challenging and may require multi-modal imaging including cardiac computed tomography to quantify the degree of valvular calcification.

Choice of Intervention

The evidence guiding the choice between surgical (SAVR) versus transcatheter intervention (transcatheter aortic valve implantation [TAVI]) continues to evolve.[11,12] Although the specific details of the major European and North American guidelines differ, the principle recommendations concur.[6,7] TAVI is associated with lower procedural mortality risk and reduced hospital length of stay but with higher rates of vascular complications, pacemaker implantation, paravalvular regurgitation and need for reintervention. SAVR results in more frequent severe bleeding, acute kidney injury and new-onset AF. Therefore SAVR is favoured in younger patients with low surgical risk (whereby valve durability is paramount) whereas TAVI is preferred in older patients or those with prohibitive surgical risk on the condition that predicted post-TAVI survival is greater than 12 months.[6,7] However, in all cases, multidisciplinary assessment by a Heart Valve Team is recommended.

As a standalone intervention, percutaneous aortic balloon dilatation offers limited magnitude and duration of benefit but may be considered as a bridge to SAVR or TAVI in patients requiring rescue from severe symptoms or haemodynamic deterioration.

Post-Intervention Management

For SAVR patients, an almost ubiquitous feature is LV diastolic dysfunction. This can be exacerbated by injury related to inadequate myocardial protection associated with LV hypertrophy. Maintaining AV synchrony is crucial and carries particular weight if temporary pacing is required. The sudden reduction in afterload can produce a low-output state associated with a hypertrophic, hyperdynamic, small-cavity LV or ‘suicide ventricle’. This may mimic systolic dysfunction or even pericardial tamponade, as despite the small chamber size, ‘filling pressures’ will be elevated with low cardiac output. Inotropic agents, including vasopressors with beta-agonist activity and IABC, can exacerbate the problem, so echocardiography is critical in defining the haemodynamic state. This will confirm small cavity size with preserved systolic function, coupled with colour and spectral Doppler findings of flow acceleration and high-velocity gradients across the left ventricular outflow tract (LVOT) or LV cavity proper. Transoesophageal echocardiography (TOE) is usually required to ensure that local chamber compression or right-sided dysfunction is not contributing to low LV preload. Combined right ventricular (RV) dysfunction is especially challenging because this can produce a series of competing interests. For example, positive inotropes may be indicated for RV systolic dysfunction, but this may adversely affect the LV as above. In this situation, selective pulmonary vasodilators and early spontaneous ventilation with minimal positive end-expiratory pressure (PEEP) should be considered as this reduces RV afterload but increases that of the left ventricle.

For the TAVI cohort, many of these physiological changes also apply but typically post-procedural progress is determined by intra-procedural complications and pre-existing co-morbidity.

Aortic regurgitation

Chronic aortic regurgitation (AR) generally progresses slowly with a protracted interval to development of LV dilatation, dysfunction and symptoms. However, unlike AS, once symptoms develop, LV systolic dysfunction is usually evident. The most common causes relate to the valve itself (congenital bicuspid aortic valve, degenerative calcific disease) or due to aortic root dilatation (as occurs in Marfan syndrome). Rheumatic disease is the predominant aetiology in developing countries. Acute AR places an acute volume load on the LV, which can result in pulmonary oedema and low cardiac output, requiring urgent surgical intervention. Typical causes include infective endocarditis (IE) and aortic dissection.

Medical Management

In acute AR, a generous heart rate will reduce the regurgitant volume, but medical management is essentially supportive. Unlike other aetiologies of cardiogenic shock, AR represents a contraindication to IABC. The main conundrum is balancing an adequate perfusion pressure, including the coronary circulation, without worsening regurgitant volume and further LV dilatation. In acute AR, these goals may be mutually exclusive and hence the need for urgent surgery. For chronic AR, afterload reduction with ACEI or dihydropyridines may provide symptomatic benefit. [6]

Intervention for Aortic Regurgitation

For AR warranting surgical intervention, the anatomical conditions are generally less favourable towards repair and so AVR is required. Indications include symptomatic patients with severe AR irrespective of LV function, or in the absence of symptoms, when LV dysfunction ensues or if undergoing cardiac surgery for unrelated indications. Whether AVR is indicated for AR or AS, it is also important to assess for dilatation of the aorta (aortopathy) as this may also warrant aortic root replacement. In selected patients, valve-sparing root replacement may be a feasible option, and less commonly, valve repair alone or the Ross procedure may be feasible in experienced centres. Due to fundamental anatomical differences, the success of TAVI for AS has not yet been replicated in patients with isolated AR. [4] Survival following AVR is strongly related to preoperative symptoms, with worse outcomes once patients reach New York Heart Association class III symptoms or have reduced exercise capacity. Surgical risk is also increased as LV function deteriorates. Nonetheless, even in patients with both symptoms and LV dysfunction, surgery is still recommended over medical therapy.[6,7]

Post-Operative Management

The post-operative course will be largely determined by the underlying degree of systolic LV dysfunction and, if present, pulmonary hypertension (PHT) and RV failure. Inotropic and vasopressor support will be simplified with the correction of AR, and there is the potential for significant improvements in function even in patients with a poor baseline state.

Mitral regurgitation

Mitral regurgitation (MR) poses a volume load on the LV with progressive left atrial (LA) and LV dilatation. Although this chamber remodelling preserves forward stroke volume, eventually systolic dysfunction occurs and cardiac output deteriorates. Since MR represents a low-afterload state, echocardiography will tend to overestimate LV systolic function. This is often illustrated post-operatively when mitral valve repair or replacement unmasks the degree of underlying LV dysfunction.

Understanding the mechanism of MR is important in detecting associated pathology and determining optimal treatment. MR can be classified as primary, referring to intrinsic pathology of the valve apparatus (leaflets, chordae tendineae, papillary muscles) or secondary (functional) MR in which the valve is structurally sound but with abnormal function due to LV dilatation and remodelling. Alternatively, the Carpentier classification is determined by leaflet motion as being normal, restricted or excessive. In high-income countries, the most common aetiologies of MR are degenerative disease with mitral valve prolapse (a primary cause) and coronary heart disease (a secondary cause).

Acute MR represents a distinct clinical entity to chronic MR, often presenting dramatically with florid pulmonary oedema and shock. In this scenario, the LA is unable to accommodate the high regurgitant volume under high pressure with subsequent pulmonary venous hypertension, acute pulmonary arterial hypertension and potentially overt RV failure. The non-dilated LV is hyperdynamic with a high ejection fraction but a low forward stroke volume. Causes include spontaneous chordal rupture with degenerative disease, leaflet perforation with IE and papillary muscle rupture due to myocardial infarction. This condition can be difficult to diagnose, sometimes mimicking severe pneumonia or ARDS, and is particularly challenging if only unilateral pulmonary oedema is present due to an eccentrically directed MR jet.

Medical Management

For the intensivist, the management of MR is highly dependent on its temporal nature (acute vs. chronic) and aetiology (primary vs. secondary). By its dynamic nature, MR can be uniquely challenging to the intensivist. Unlike stenotic lesions with relatively fixed stroke volume, the haemodynamic perturbation associated with MR can be profoundly influenced by loading conditions, the state of inotropy and heart-lung interaction.

Acute MR

Acute MR will almost always require urgent surgical intervention. Beyond establishing an early diagnosis, frequent communication between intensive care and surgical teams is crucial in determining the timing of surgery prior to attempts at stabilisation. Key measures include positive pressure ventilation with sufficient PEEP; IABC is invaluable by simultaneously reducing afterload as well as increasing systemic mean arterial pressure. Further afterload reduction with vasodilators is ideal, but systemic hypotension is often a limiting factor and rather, vasopressors are more often required. Additional mechanical support may play a role but ultimately the answer is expeditious surgery.

Chronic MR

In the critically ill patient, chronic MR may manifest as various syndromes, often exacerbating the management of an unrelated presenting illness.

Inotropic agents offer variable recruitment in LV function and hence forward stroke volume. Afterload reduction is key but often a compromise needs to be reached between acceptably low systemic arterial pressure and higher forward flow (as occurs in AR as discussed earlier).

Intervention for Mitral Regurgitation

Primary MR

MV surgery is recommended in symptomatic patients with severe chronic primary MR irrespective of LV function on the condition that the surgical risk is deemed acceptable. For asymptomatic patients, evidence of deteriorating LV function (EF < 60% or chamber dilatation) should initiate consideration of intervention.[6,7] The preferred surgical option in all cases of primary MR is repair over replacement, especially if the disease is limited to the posterior leaflet.[7,10] Repair has advantages including preservation of LV function and lower operative mortality, the avoidance of thromboembolic risk of mechanical valves and the inevitable deterioration of bioprosthetic valves. The balance swings towards MV replacement (MVR) as the chance of successful and durable repair diminishes (e.g. complex anterior and posterior leaflet disease).

For patients with high surgical risk, transcatheter repair may be considered.[7,10] Based on the principles of the Alfieri method of tethering the anterior and posterior leaflets, transcatheter ‘edge-to-edge’ repair (TEER) has been the most successfully demonstrated percutaneous alternative to open surgery. Although resulting in greater residual MR than standard open surgical approaches, TEER is a safe and feasible option if anatomical factors are favourable. The role of transcatheter mitral valve replacement is currently undergoing investigation.[5]

Secondary MR

Repair or replacement should only be considered in patients with persistent symptoms despite optimal goal-directed medical management.[6,13] Surgical intervention is reasonable in patients undergoing simultaneous

AVR or coronary artery bypass grafting. [7] Notably, secondary MR is currently the most common indication for TEER in Europe. [14]

Post-Operative Management

Key considerations post-operatively are the state of the pulmonary circulation and RV function. Commonly, previously underestimated LV systolic dysfunction will manifest as afterload is now increased. A specific complication of MV repair warrants discussion as delayed recognition can be disastrous: LVOT obstruction with systolic anterior motion of the anterior leaflet. This can be induced if there is excessive posterior leaflet length or if associated with septal hypertrophy. [15], [16] This state of low cardiac output with dynamic LV function can be particularly unnerving for the intensivist, as management requires a contrarian approach: volume loading, administration of pure vasoconstrictors and cessation of positive inotropes and inducing negative inotropy with beta-blockade. All these manoeuvres should be guided in real-time by echocardiography. This is a particularly dynamic condition in which the patient's state can change markedly within a matter of seconds to minutes. Ideally, the condition is identified in the operating room following weaning of cardiopulmonary bypass, as re-operation with MVR may be required.

Mitral stenosis

Mitral stenosis (MS) is predominantly due to rheumatic and degenerative disease. Ironically, being a left-sided valve disease, LV function is usually unaffected. The major clinical issues are LA hypertension with resultant PHT, RV failure, atrial arrhythmia and heightened thromboembolic risk.

Medical Management

If severe MS is the main driver for critical care unit admission then percutaneous or surgical intervention will be required. Controlling the ventricular rate is crucial to maximise the diastolic interval with atrial fibrillation (AF) being both common (occurring in 30%–40% of patients) and poorly tolerated. Anticoagulation is recommended in the presence of AF (paroxysmal, persistent or permanent), a prior embolic event or LA thrombus.

Intervention for Mitral Stenosis

Severe MR is characterised by mitral valve area ≤1.5 cm^2; a mean transvalvular gradient >10 mm Hg usually correlates with severe disease. Percutaneous mitral balloon commissurotomy (PMBC) is the preferred option in symptomatic patients with severe MS and favourable valve morphology (relatively thin, mobile leaflets and free of calcium).[4, 17] Open surgery is recommended in symptomatic patients who are not candidates for PMBC, or if undergoing cardiac surgery for other indications.

Post-Operative Management

Since isolated MS does not cause substantive detriment to LV function, post-operative attention is focused on pulmonary circulation and RV function. With correction of MS, LA and right-sided pressures should immediately improve. However, the insults of cardiopulmonary bypass and aortic cross-clamping can be significant, and RV dysfunction can be a challenge, especially if PHT remains largely fixed and irreversible.

Right-Sided Valvular Lesions

Isolated valve lesions of the right heart are less commonly encountered in adult critical care practice. Occasional cases requiring surgery may relate to IE or residual and uncorrected congenital heart disease (CHD), such as severe pulmonary regurgitation (PR) following Tetralogy of Fallot (TOF) repair. Any primary valvular disease associated with symptoms or RV dilatation warrants surgical intervention.

Tricuspid regurgitation (TR) is almost ubiquitous in patients with left-sided heart disease. A common dilemma is when to perform simultaneous tricuspid valve repair or replacement in patients undergoing left-sided valvular surgery. Repair in particular does not add appreciably to the risks of surgery and should be performed in cases of severe TR or severe tricuspid annular dilatation, although this remains underutilised in current practice. However, careful consideration is required in the presence of severe RV dysfunction or significant PHT, as such repair can provoke catastrophic RV failure. Transcatheter techniques for both valve repair and replacement are available with emerging data to guide practice.[18,19]

Valvular Heart Disease in Pregnancy

For native VHD in pregnancy, the highest-risk lesions are those that are stenotic rather than regurgitant, and left- rather than right-sided. Pregnancy-associated haemodynamic changes include increased heart rate and decreased systemic vascular resistance (SVR), which are favourable conditions for regurgitant faults, but disadvantageous for those stenotic.[20,21] With severely stenotic lesions, cardiac output may not realise the usual 50% increase that is reached by the end of the second trimester.

Prior to pregnancy, intervention for stenotic lesions is recommended in severe AS with symptoms and for severe MS (with preference for PMBC) regardless of symptoms.[4,22] For severe regurgitant lesions, repair or replacement is indicated for symptomatic women.[4,22] In pregnant patients, severe MS is poorly tolerated. PMBC is the preferred option, preferably performed after 20 weeks gestation, otherwise, surgical MVR carries a significant risk of both foetal (15%–56%) and maternal (9%) mortality.[4]

Adult Congenital Heart Disease

Congenital heart disease (CHD) is common. Birth prevalence is estimated to be close to 9 per 1000 live births.[23] Advances in diagnosis and management of paediatric CHD have allowed for improved survival into adulthood, shifting burden of disease into the adult population. In developed countries, almost 90% of children survive to adulthood, with adult survivors outnumbering affected children and adolescents.[24–26] However, the same gains have not been realised in low- and middle-income countries with the burden of disease only increasing.[27,28] Adult CHD (ACHD) is highly variable in complexity and presentation, with arrhythmias, sepsis, heart failure (HF) or hepatic failure leading to most intensive care admissions.[29] HF is the current leading cause of death.[30, 31]

The Intensivist Perspective

Despite extensive guidelines published for the general management of ACHD, those applicable to the intensive care setting are limited.[32–34] Owing to the complexity and heterogeneity of ACHD patients, those who are critically ill present unique challenges to the intensivist. One must appreciate the underlying anatomical diagnosis and pathophysiology, the history of corrective procedures, the anticipated late complications, the associated systemic disease and the holistic consideration of cardiopulmonary interaction (Tables 34.3 – 34.5).

Table 34.3

Considerations for the intensivist managing adult congenital heart disease

QUESTION	COMMENTS
What is the congenital diagnosis and history of corrective procedures?	Appreciate natural history, anatomy and post-procedural residual abnormalities or anticipated complications (see Tables 34.4 , 34.5)
Are there residual shunts and what is the direction of flow?	Consider effects of altering PVR:SVR relationship [a] on shunt direction, oxygenation and cardiac output Potential paradoxical embolisation risk Cyanosis and hyperviscosity syndrome if significant R→L shunt
Which morphological ventricle is the systemic ventricle (subaortic)?	Look for history of transposition (morphological RV is the systemic ventricle in l-TGA or d-TGA with atrial switch)
Is pulmonary hypertension an expected feature?	May be prominent with residual shunts, but also occurs with congenital or acquired left heart and pulmonary disease RVF may be the predominant haemodynamic issue
Is PVR critically important?	Especially important with single ventricle ('Fontan' circulation) Also, consider influence of PVR on residual shunt lesions

QUESTION	COMMENTS
What influence will positive pressure ventilation have on cardiopulmonary interaction?	Possibly beneficial with: left heart dysfunction (↓ LV wall stress) Possibly detrimental with: Fontan circulation, RVF, significant TR and PHT, shunts (↑ RV afterload and ↓ preload)
Is there a preload-dependent state?	Caution with Fontan circulation, Eisenmenger syndrome, LVOT obstruction
Is particular caution required with negative inotropic or vasodilatory drugs?	Beware heart failure syndromes and pulmonary hypertension With shunts, consider effect on changing ratio of SVR:PVR Caution ↓ SVR with left-sided obstructive lesions
Does IV access present any issues?	Potential difficulty if history of multiple interventions In Fontan circulation, standard CVC approach will enter PA and transvenous ventricular pacing is not possible
Are arrhythmias a feature and is a device (PPM, AICD) in situ?	Consider device interrogation

[a] Factors ↑ PVR: Hypoxia, hypercarbia, high haematocrit, positive pressure ventilation, hypothermia, metabolic acidosis, alpha-adrenergic stimulation.

Factors ↓ SVR: Vasodilators, general anaesthesia, hyperthermia.

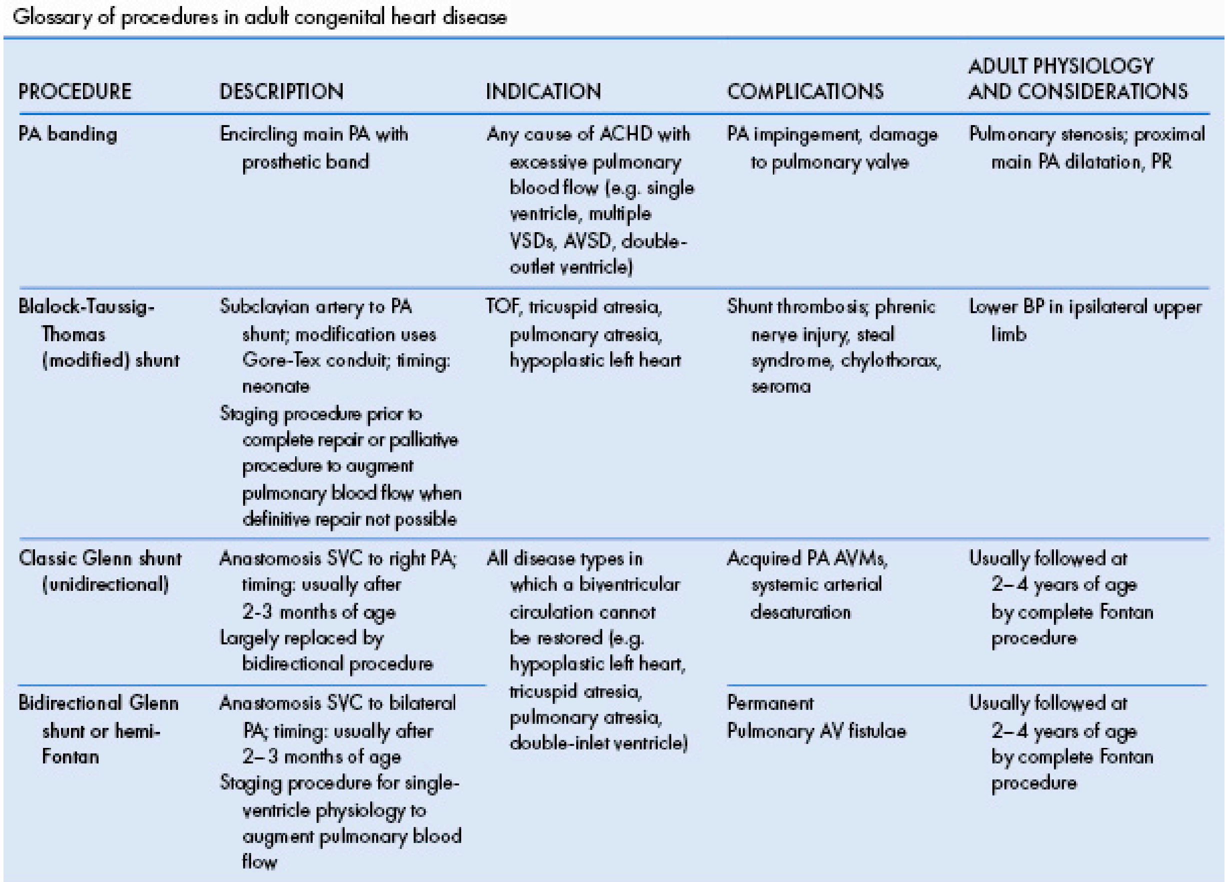
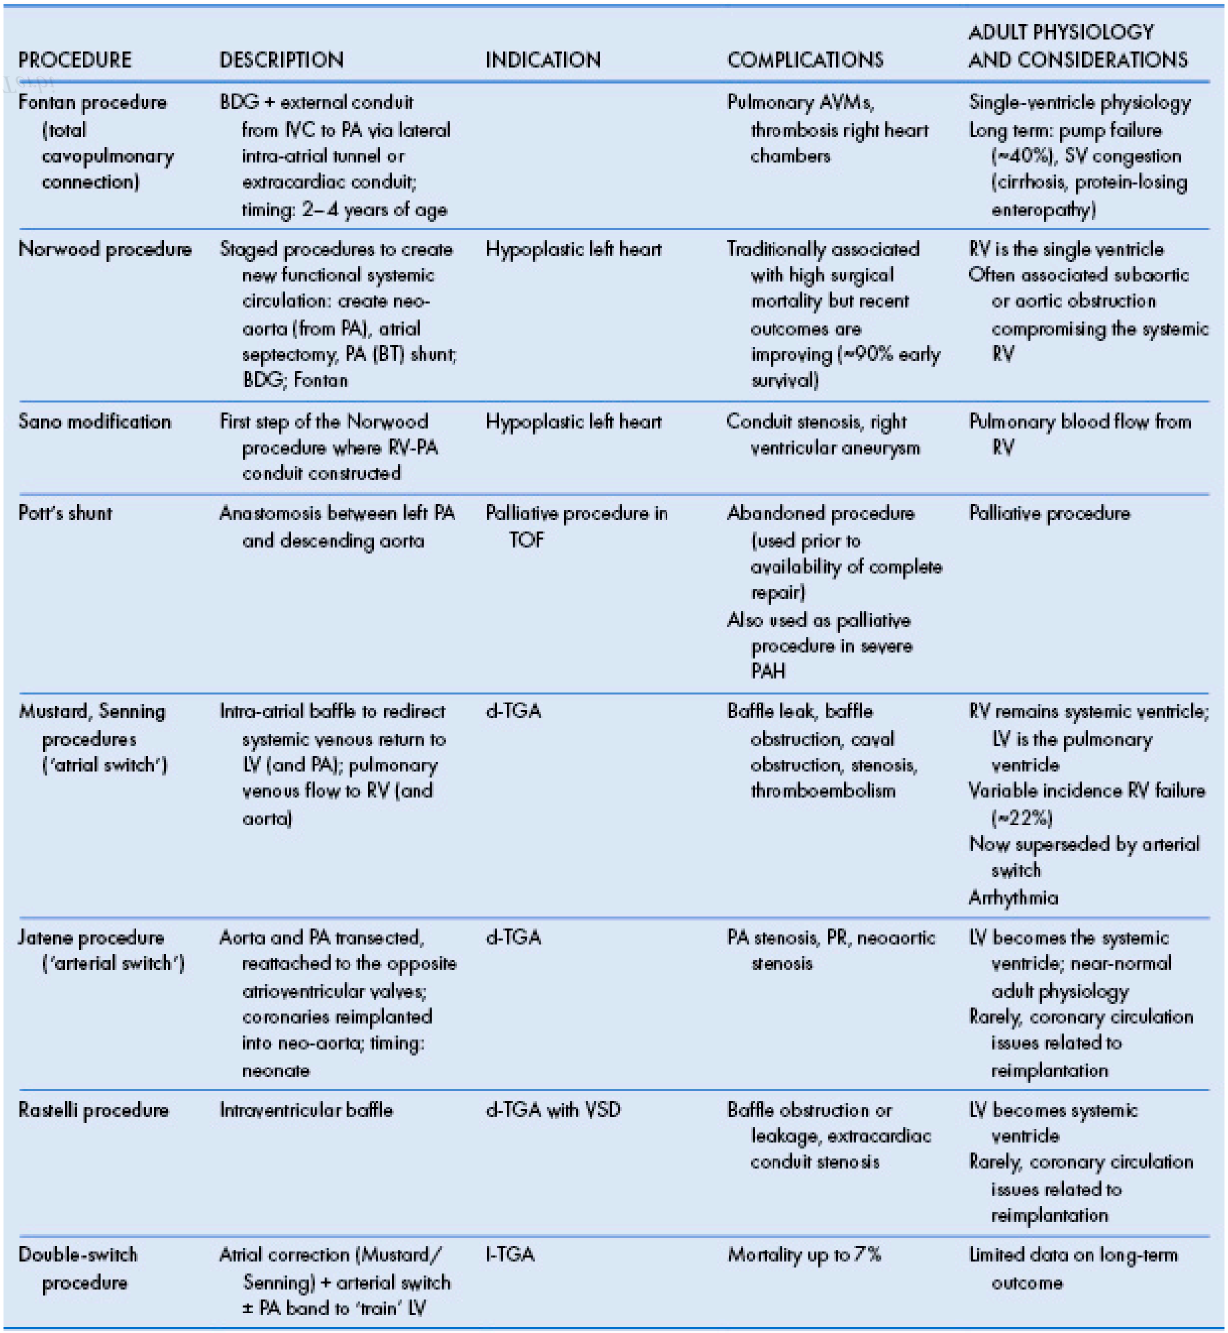
Table 34.5



Glossary of procedures in adult congenital heart disease

PROCEDURE	DESCRIPTION	INDICATION	COMPLICATIONS	ADULT PHYSIOLOGY AND CONSIDERATIONS
PA banding	Encircling main PA with prosthetic band	Any cause of ACHD with excessive pulmonary blood flow (e.g. single ventricle, multiple VSDs, AVSD, double-outlet ventricle)	PA impingement, damage to pulmonary valve	Pulmonary stenosis; proximal main PA dilatation, PR
Blalock-Taussig-Thomas (modified) shunt	Subclavian artery to PA shunt; modification uses Gore-Tex conduit; timing: neonate Staging procedure prior to complete repair or palliative procedure to augment pulmonary blood flow when definitive repair not possible	TOF, tricuspid atresia, pulmonary atresia, hypoplastic left heart	Shunt thrombosis; phrenic nerve injury, steal syndrome, chylothorax, seroma	Lower BP in ipsilateral upper limb
Classic Glenn shunt (unidirectional)	Anastomosis SVC to right PA; timing: usually after 2-3 months of age Largely replaced by bidirectional procedure	All disease types in which a biventricular circulation cannot be restored (e.g. hypoplastic left heart, tricuspid atresia, pulmonary atresia, double-inlet ventricle)	Acquired PA AVMs, systemic arterial desaturation	Usually followed at 2–4 years of age by complete Fontan procedure
Bidirectional Glenn shunt or hemi-Fontan	Anastomosis SVC to bilateral PA; timing: usually after 2–3 months of age Staging procedure for single-ventricle physiology to augment pulmonary blood flow		Permanent Pulmonary AV fistulae	Usually followed at 2–4 years of age by complete Fontan procedure



PROCEDURE	DESCRIPTION	INDICATION	COMPLICATIONS	ADULT PHYSIOLOGY AND CONSIDERATIONS
Fontan procedure (total cavopulmonary connection)	BDG + external conduit from IVC to PA via lateral intra-atrial tunnel or extracardiac conduit; timing: 2–4 years of age		Pulmonary AVMs, thrombosis right heart chambers	Single-ventricle physiology Long term: pump failure (~40%), SV congestion (cirrhosis, protein-losing enteropathy)
Norwood procedure	Staged procedures to create new functional systemic circulation: create neo-aorta (from PA), atrial septectomy, PA (BT) shunt; BDG; Fontan	Hypoplastic left heart	Traditionally associated with high surgical mortality but recent outcomes are improving (~90% early survival)	RV is the single ventricle Often associated subaortic or aortic obstruction compromising the systemic RV
Sano modification	First step of the Norwood procedure where RV-PA conduit constructed	Hypoplastic left heart	Conduit stenosis, right ventricular aneurysm	Pulmonary blood flow from RV
Pott's shunt	Anastomosis between left PA and descending aorta	Palliative procedure in TOF	Abandoned procedure (used prior to availability of complete repair) Also used as palliative procedure in severe PAH	Palliative procedure
Mustard, Senning procedures ('atrial switch')	Intra-atrial baffle to redirect systemic venous return to LV (and PA); pulmonary venous flow to RV (and aorta)	d-TGA	Baffle leak, baffle obstruction, caval obstruction, stenosis, thromboembolism	RV remains systemic ventricle; LV is the pulmonary ventricle Variable incidence RV failure (~22%) Now superseded by arterial switch Arrhythmia
Jatene procedure ('arterial switch')	Aorta and PA transected, reattached to the opposite atrioventricular valves; coronaries reimplanted into neo-aorta; timing: neonate	d-TGA	PA stenosis, PR, neoaortic stenosis	LV becomes the systemic ventricle; near-normal adult physiology Rarely, coronary circulation issues related to reimplantation
Rastelli procedure	Intraventricular baffle	d-TGA with VSD	Baffle obstruction or leakage, extracardiac conduit stenosis	LV becomes systemic ventricle Rarely, coronary circulation issues related to reimplantation
Double-switch procedure	Atrial correction (Mustard/Senning) + arterial switch ± PA band to 'train' LV	l-TGA	Mortality up to 7%	Limited data on long-term outcome

Key clinical scenarios and syndromes

Heart Failure in Adult Congenital Heart Disease

Diagnosis of HF in ACHD is difficult. Presentation often includes atypical symptoms, treatment is often extrapolated from the general population and prognostic tools such as the New York Heart Association Classification are not validated for use in the palliated ACHD population (e.g. those without definitive corrective surgery).[41, 42] Guidelines from major societies for management of HF in ACHD apply specifically to the outpatient setting, except for a recent European Society of Cardiology statement aimed at the emergency setting.[25, 43–45] Contrasting expert opinions on recommendations for management of ACHD highlights the paucity of high-quality evidence. Scientific trials to guide intensivists on managing the critically unwell ACHD patient do not exist. An approach based on pathophysiological first principles and the recognition of specific symptoms (below) is paramount. Reversible causes should be sought and treated (e.g. arrhythmia, sepsis) and intervention for structural causes (e.g. outflow obstruction or residual shunt) should be considered. Generic, acquired contributors to ventricular dysfunction (e.g. coronary artery disease) should not be discounted, especially as the incidence of these increases with the ageing ACHD population.[46] Management is tailored according to the individual anatomy and pathophysiology of the patient, for example between single-ventricle or biventricular circulation, subpulmonic or subaortic ventricular dysfunction and diastolic or systolic dysfunction. Whilst standard HF therapy can be applied to ACHD patients with biventricular circulation, an understanding of how the individual patient will react to vasoactive agents and positive pressure ventilation is critical. The patients at highest risk for the development of HF are those with a single ventricle palliated with a Fontan procedure, TOF patients with residual PR and those with a systemic right ventricle (RV), as discussed below.

Shunts, pulmonary vascular disease and pulmonary hypertension

ACHD results in pulmonary hypertension in 3%–7% of patients.[47] Systemic to pulmonary shunting exposes the pulmonary vasculature to increased blood flow and pressure, which may lead to obstructive arteriopathy with increased pulmonary vascular resistance (PVR). At the extreme, when PVR approaches and exceeds SVR, the shunt is reversed (Eisenmenger syndrome).

For adult patients with simple shunts repaired as young children, the prognosis is excellent. However, lesions are often only diagnosed once symptoms develop in adulthood. The role of shunt correction in these situations is less well-defined. This requires assessment of the defect, the patient’s age, the PVR:SVR ratio, or the ratio of pulmonary to systemic systolic pressure (PASP:SASP) and the ratio of pulmonary to systemic flow (Qp:Qs).[43,44] Somewhat paradoxically, the left-to-right shunt must be large enough to warrant surgery, but the risk becomes prohibitive once significant pulmonary hypertension is present. Shunt closure is contraindicated if there is severe pulmonary hypertension.[44] Indications for closure of atrial septal defects (ASDs) and ventricular septal defects (VSDs) vary between societies in most recent guidelines (Table 34.6). RV volume overload will occur with left-to-right shunting through an ASD. LV volume overload results from a VSD due to a compensatory increase in intravascular volume that acts to maintain LV diastolic volume and systemic cardiac output. Percutaneous device insertion is the preferred method for secundum ASD closure, whereas for VSD pericardial patch repair is preferred if the surgical risk is acceptable.[44] Patients who develop pulmonary hypertension after shunt closure have a poor prognosis.

Table 34.6

Recommendations for closure of simple congenital shunts

	ASD	VSD
ESC	RV overload without pulmonary hypertension (PVR <3 Wood units) AND without LV disease	LV overload without pulmonary hypertension (PVR <3 Wood units)
AHA/ACC	Qp:Qs ≥1.5 AND symptoms of RV overload, without cyanosis AND PASP:SASP <50% or PVR:SVR <1/3	Qp:Qs ≥1.5 AND PASP:SASP <50% or PVR:SVR <1/3
CCS	Symptomatic; RV overload AND/OR Qp:Qs ≥1.5 without pulmonary hypertension (PAP <50% systemic and/or PVR <1/3 SVR) AND without LV disease	LV overload without pulmonary hypertension (PAP <50% systemic and/or PVR <1/3 SVR)

ACC, American College of Cardiology; *AHA* , American Heart Association; *ASD* , atrial septal defect; *CCS,* Canadian Cardiovascular Society; *ESC* , European Society of Cardiology; *LV,* left ventricle; *PDA,* patent ductus arteriosus; *RV,* right ventricle; *VSD,* ventricular septal defect.

See references 36 , 43 , 44 .

In the case of residual shunting, the SVR:PVR balance (see Table 34.3) will determine the magnitude and direction of the shunt, affecting systemic cardiac output, the degree of hypoxaemia and the risk of systemic embolisation. For the most severely affected patients with Eisenmenger syndrome, bosentan is recommended if World Health Organisation Functional class III symptoms are present.[47, 48] A recent small randomised control trial found no difference in effect between macitentan and placebo on 6-minute walk duration in paediatric patients with Eisenmenger syndrome.[49] However, other endothelin-receptor antagonists and pulmonary vasodilators (e.g. prostanoids and phosphodiesterase type 5 inhibitors) may be considered, despite lacking a robust evidence base. Secondary erythrocytosis is generally tolerated unless haematocrit is greater than 65% and is associated with hyperviscosity symptoms. For the intensivist, management can be extremely challenging. Prioritising the pulmonary circulation may warrant subtle but deliberate changes to practice to optimise PVR, such as ‘earlier’ use of renal replacement therapy to correct metabolic acidosis, preferential use of non-catecholamines (e.g. vasopressin) for defending systemic (coronary perfusion) pressure,[50,51] re-evaluation of haematocrit targets, cautious/selective use of sedative/hypnotic agents, use of intravenous or inhaled selective pulmonary vasodilator therapy, judicious use of non-invasive ventilation and meticulous attention to carbon dioxide tension when controlled positive pressure ventilation is mandated.

Tetralogy of Fallot

TOF is the most common cyanotic CHD in adults. For patients with lesions repaired in childhood, the prognosis is excellent. Significant PR is the most frequent complication; although well tolerated for years, PR eventually leads to RV dilatation and dysfunction, making optimal timing of valve replacement challenging. Additional long-term complications include residual VSD or RV outflow tract obstruction, aortic root dilatation and arrhythmia. Left-sided ventricular dysfunction is being increasingly recognised, largely due to interventricular interaction including abnormal septal configuration and electromechanical dyssynchrony.

The Morphological RV as the Systemic Ventricle

A systemic right ventricle is destined to fail. This group largely includes patients with dextro-transposition of the great arteries (d-TGA; palliated with atrial switch) or levo-transposition of the great arteries (l-TGA). In addition to RV systolic dysfunction, d-TGA patients who have undergone atrial switch (Mustard or Senning procedures) are often limited by fixed stroke volume due to limited flow through stiff atrial baffles. These complications do not occur with the more recent arterial switch procedures, in which normal atrioventricular and ventriculoarterial connections are restored. Patients with l-TGA (where connections are 'congenital corrected') often develop progressive systemic AV regurgitation and arrhythmia is common.

Fontan Circulation (Single-Ventricle Physiology)

This group includes tricuspid atresia, double-inlet LV and hypoplastic left heart syndrome. Surgical correction bypasses systemic venous return around the subpulmonary ventricle; all systemic venous blood returns directly to the lungs via passive flow through the pulmonary arteries. These patients are at high risk for HF. The lack of a subpulmonic ventricle requires a central venous pressure higher than the mean pulmonary arterial and pulmonary venous pressure to maintain return to the single ventricle. The circulation is thus 'preload'-dependent, but PVR is critically important (see above). Although these patients have high afterload and stroke-work, there is no clinical trial evidence to guide the use of specific afterload-reducing therapy. Pulmonary vasodilator therapies have shown mixed results.[47], [52] Long-term complications include cirrhosis, portal hypertension and protein-losing enteropathy.

Systolic Failure of the Morphological Left Ventricle

Systolic LV dysfunction may result from pressure-overloaded lesions such as congenital AS, bicuspid aortic valve and coarctation of the aorta. Bicuspid valves may develop progressive insufficiency as well as aortic root dilatation and dissection. Culprit volume-overload lesions include AG, VSD, patent ductus arteriosus or MR. Although specific trials in ACHD patients with hard endpoints are lacking, current treatment guidelines extrapolate data from the general HF population to include recommendations for diuretics, renin-angiotensin-aldosterone system antagonists, beta blockers and mineralocorticoid receptor antagonists.

Transplantation

Compared to patients without CHD, adult patients with CHD undergoing heart transplantation have lower early (30-day) survival rates, but higher long-term survival rates with similar 10-year outcomes.[25,53,54] The timing of assessment for transplant is difficult, and patients with irreversible multisystem dysfunction may require combined multiorgan transplantation (e.g. pulmonary, hepatic or renal). Single-ventricle anatomy, anatomic complexity and protein-losing enteropathy have been identified as risk factors for poor outcomes.[30]

Role of mechanical circulatory support and ventricular assist devices

Although low survival rates and an increased length of stay have been shown in retrospective data from extracorporeal membrane oxygenation (ECMO) utilisation in ACHD patients, ECMO may be considered in those with decompensated HF and cardiogenic shock, or as a procedural bridge.[45,35] Anatomy, pathophysiology and vascular complications are key considerations for ECMO cannulation and flow.

Data published recently found ACHD with left ventricular assist devices (VADs) implantation to have comparable survival outcomes in comparison to the general population with left VAD, but higher mortality in ACHD with bi-VAD or total artificial heart implanted.[55,56] At present the utilisation of VADs is lower in ACHD awaiting transplantation than those with acquired heart disease. ACHD patients are more likely to have right-sided HF, pulmonary hypertension, or residual shunts which may make them less appealing candidates for VADs.

Arrhythmia

A gamut of tachy- and bradyarrhythmias may become manifest in ACHD patients, with arrhythmias now a major cause of morbidity and mortality. Supraventricular tachycardias (SVTs), especially AF and interatrial reentry tachycardia (IART), occur in up to 50% of CHD. Electrical cardioversion is recommended in unstable patient with arrhythmia, both atrial and ventricular.[45] Catheter ablation is recommended for AF and IART in ACHD lasting ≥48 hours in the haemodynamically stable patient.[44] Sudden cardiac death (SCD) accounts for 20%–30% of late deaths in ACHD patients with systemic ventricular dysfunction a key risk factor.[57, 58] Selection criteria for implantable cardioverter defibrillator devices as primary or secondary prevention of SCD are based on data extrapolated from the generalised population.[30, 59] Specific planning for catheter ablation and device implantation may be required with consideration of anatomy and vascular pathways.[60, 61]

Infective Endocarditis

ACHD patients have a greater (15- to 140-fold) incidence of IE than the general population.[44] Echocardiographic diagnosis can be difficult, with disease more often involving the right side, but overall prognosis is better than other patient groups, with mortality less than 10%.

Non-Cardiac Disease and Other Considerations in Adult Congenital Heart Disease

Non-cardiovascular morbidity may relate to the underlying lesion, surgical repair, or medical treatment. Neurological complications include embolic stroke, intracranial haemorrhage and brain abscess. Coarctation and bicuspid aortic valve are associated with an increased risk of intracranial aneurysms.[62, 63] Pulmonary abnormalities most commonly manifest as restrictive ventilatory defects and renal dysfunction is present in approximately 50% of the ACHD population.[64, 65] In addition to associated congenital airway abnormalities, previous prolonged intubation can result in subglottic stenosis or vocal cord paresis. Congestive hepatopathy occurs chiefly in Fontan patients and those with RV failure. Due to radiation exposure, especially in childhood, patients with ACHD are possibly at increased cancer risk, particularly for haematological and head/neck malignancies.[66, 67] Pregnancy in CHD is associated with an increased rate of maternal and neonatal adverse events.[22, 30, 44, 68, 69] Groups at highest risk during pregnancy include those with severe pulmonary arterial hypertension, left heart obstruction, poor systemic ventricular function and aortic root dilatation.[68, 70]

Infective Endocarditis

IE can be a taxing disease for the intensivist. In critically unwell patients managed in the ICU, the short-term mortality approximates 30%–57% in those treated aggressively with surgery; whereas for patients meeting an indication but denied surgery, the prognosis is dismal with a mortality of 85%.[70-74] Common reasons for ICU admission include HF in over 60% of cases, septic shock in 20% and neurological sequelae in 15%.[74] Staphylococci have emerged as the most prevalent culprit organisms overall, although alternative organisms, such as fungi are proportionately more common in the ICU population. Overall, the incidence of IE is increasing with transforming epidemiology: mean age at diagnosis is increasing with an increasing proportion related to prosthetic valves, cardiac devices and other nosocomial factors whilst the proportion associated with rheumatic heart disease is decreasing.[75, 76] This is consistent with the pathophysiology of the disease, whereby an initial insult or injury to the valvular endothelium is required: this then triggers platelet and fibrin deposition; a sterile vegetation is formed which in turn can become infected if encountered by bloodborne organisms.

Diagnosis

Although widely cited and applied, the modified Duke criteria lack accuracy for early diagnosis with sensitivity at best estimated to be 80%.[77,78] In this context, the criteria are intended as a guide and must not replace clinical judgement. Diagnosis in ICU patients can be particularly challenging. This requires holding a high index of suspicion, searching meticulously for clinical features, such as fever, vascular and immunological phenomena and arranging appropriate microbiological testing. Echocardiography is cornerstone, with major features including vegetations (defined as oscillating intracardiac masses on valve or supporting structures), abscess, new partial dehiscence of prosthetic valve and new valvular regurgitation (Table 34.7). Recent guidelines suggest additional imaging modalities may be of use.[77,79] In doubtful cases, cardiac multislice computed tomography (CT) may better detect local paravalvular complications (abscesses and pseudo-aneurysms); CT and magnetic resonance imaging may detect distant embolic phenomena; 18F-fluorodeoxyglucose positron emission tomography/CT may detect prosthetic valve infection, but sensitivity and specificity for native disease remains poorly tested.[80]

Table 34.7

Echocardiographic features of infective endocarditis

FEATURE	DESCRIPTION
Vegetations [a]	Shape: usually amorphous, shaggy, lobulated, less commonly linear or round Motion: high-frequency flutter, oscillating, chaotic, orbiting Location: typically atrial side of atrioventricular valves, ventricular side of the aortic valve
Valvular disease	New regurgitation [a] , leaflet perforation or destruction
Abscess [a]	Echolucent or echogenic-heterogeneous space or tissue thickening Usually paravalvular but may affect any myocardial region Aortic valve is most commonly affected
Pseudoaneurysm	Pulsatile perivalvular echo-free space; colour-flow Doppler present
Perforation	Interruption of endocardial continuity
Fistula	Colour-Doppler communication between neighbouring cavities (e.g. aorta-ventricle or aorta-atrium)
Valve aneurysm	Saccular bulging of valvular tissue
Dehiscence of prosthetic valve [a]	Paravalvular regurgitation; rocking motion of prosthesis
Other findings	Altered left ventricular size or function Elevated left or right ventricular filling and pulmonary artery pressures

[a] Constitute the Modified Duke major echocardiographic criteria.[78]

See references 77, 81.

Role of Transoesophageal Echocardiography

Although transthoracic echocardiography (TTE) is the first-line imaging technique for suspected IE, TOE should be considered if clinical suspicion remains high with a negative TTE or there are concerns for local complications. Even after a negative TOE, if clinical suspicion remains high, a repeat study should be considered in 3–5 days.[79] Such an interval may allow vegetations to reach a detectable size or abscess cavities or fistulous tracts to be evident. For right-sided lesions, TOE is also more sensitive in diagnosing lead-associated and pulmonary-valve disease.

Antimicrobial Therapy

Early antimicrobial therapy is imperative and should reflect major society guidelines in the context of local expertise and protocols. General principles include the use of prolonged, parenteral, bactericidal therapy, recognising the altered pharmacokinetics typically seen in critically ill patients. Initial empirical therapy, whilst awaiting microbiological testing, should cover staphylococci, streptococci and enterococci in native valve endocarditis (NVE). Flucloxacillin is more effective than vancomycin for methicillin-susceptible staphylococci, but the latter should be used empirically in prosthetic valve endocarditis (PVE) and healthcare-associated IE regimens to cover methicillin-resistant strains.[77]

Indications for and Timing of Surgery

Currently, the proportion of IE patients proceeding to surgery is ≈50%. Although the theoretical indications for surgery are clear, practical application is complex and relies largely on clinical judgement, with consideration of the real-time status of the patient, the perceived natural history and the risks of surgery. Decision making in patients requiring critical care unit admission is challenging, and multidisciplinary involvement is recommended. [77] It should be noted that the bulk of the evidence and guidelines relate to left-sided endocarditis.

Heart failure

HF is the most common complication of IE and the most common indication for surgery. The usual mechanism of HF is new or progressive valvular regurgitation although intracardiac fistulae or valve obstruction may occur. In these circumstances, the European Society of Cardiology suggests ‘urgent’ surgery (within a few days), but with refractory shock or pulmonary oedema, the recommendation is for ‘emergency’ surgery (within 24 hours). [77] For similar indications, the American Heart Association guidelines only use the time discriminator of ‘early’, meaning surgery during initial hospitalisation and before completion of the antibiotic course. [79]

Uncontrolled Infection

Uncontrolled infection is described as persisting infection with ongoing positive blood cultures after an arbitrary 7–10 days of antibiotic treatment. However, recent data suggest that prognosis is worse even with only 3 days of persistently positive blood cultures. [82] Uncontrolled infection may also refer to perivalvular extension with feared complications, such as abscess formation, pseudo-aneurysms and fistulae.

Although ‘early’ or ‘urgent’ surgery is recommended for patients with uncontrolled infection, surgical outcomes for patients with overt septic shock, as opposed to cardiogenic shock, are much poorer. In practice, it may be difficult to compartmentalise the haemodynamic disturbance as purely ‘septic’ or ‘cardiogenic’. If possible, it may be preferable to attempt a period of stabilisation prior to surgical commitment. Navigating this decision-making process requires careful and repeated clinical examination, appropriate haemodynamic monitoring, including serial echocardiography and close liaison with surgical and other colleagues.

Prevention of Embolisation

Embolisation rates improve significantly with appropriate antibiotics, so prompt initiation is paramount. Only one randomised trial has examined the role of early surgery in this context.[83] The precise role of surgery remains unclear, with guidelines based on the size and mobility of the vegetation, the associated valve dysfunction and the presence of established embolic events. Adjunctive anticoagulation or antiplatelet therapy is not recommended.

Neurological Events and Risk of Surgery

Symptomatic neurological events develop in 15%–30% of all IE patients and are the most common complications in patients following ICU admission.[84] Yet, many of these patients might otherwise warrant urgent valvular surgery, with the attendant risks of systemic heparinisation and other rheological effects of cardiopulmonary bypass. Current recommendations suggest that as long as coma and intracerebral haemorrhage are absent, ischaemic stroke should not be considered a contraindication to surgery, with an estimated neurological risk in the order of 3%–6%.[77,79,84] In the case of intracerebral haemorrhage, surgery should be delayed by at least 1 month, although patients with small lesions have been operated on safely.[77,79,84] CT or MR angiography may clarify risk in these cases.[85]

Prosthetic Valve Endocarditis

PVE represents up to 30% of all IE cases.[77,86] Antimicrobial therapy for staphylococcal PVE generally warrants more prolonged treatment often in combination with aminoglycosides and rifamycins. Surgery is more likely to be required but its precise role remains controversial, and current guidelines follow similar principles to NVE.

Infective Endocarditis Associated With Cardiac Implanted Electronic Devices

IE associated with cardiac implanted electronic devices (CIEDs) is increasing, accounting for nearly 10% of all cases and is associated with high mortality. [87] *Staphylococcus aureus* and Coagulase-negative Staphylococci are the most common causative organisms. Device-related infection can manifest as IE as well as pocket abscess, erosion or lead vegetation. Diagnosis can be particularly difficult and by nature of CIED implantation, patients may inevitably have severe co-morbidity. Management requires prolonged antibiotic therapy as well as removal of the complete apparatus (leads and pulse generator); maintenance of the device is warranted only in exceptional cases. Transvenous explantation is preferred, but is not risk free, and should only be performed in centres with ready access to cardiac surgical rescue.

Right-Sided Endocarditis

Constituting 5%–10% of cases and despite a better prognosis, surgery for right-sided IE is less commonly employed but can be considered for patients with right HF due to severe TR with intractable symptoms; sustained infection caused by difficult-to-treat organisms or lack of response to appropriate antimicrobial therapy; and recurrent pulmonary embolism or paradoxical emboli despite antimicrobial therapy. Valve repair may be preferred if possible rather than replacement. [77]

Fungal endocarditis

Fungal IE accounts for 1%–3% of all cases and is more commonly seen with PVE, immunocompromised patients and in the setting of intravenous drug use. *Candida* and *Aspergillus* species are the main offenders. Surgery is more frequently required in conjunction with long-term antifungal chemotherapy. [88]

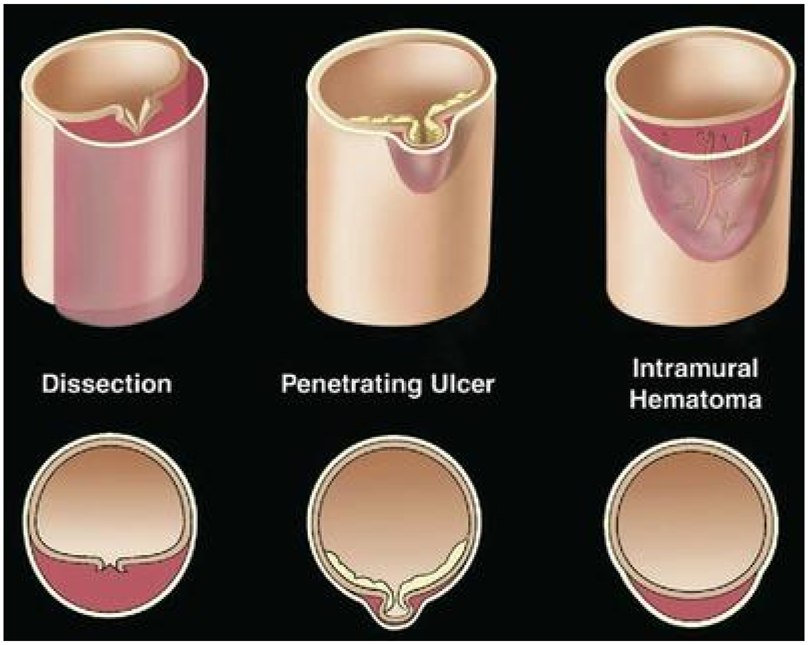
Acute aortic syndrome

Clare Quarterman

Acute Aortic Syndrome

The aorta is the largest artery of the body comprising three layers. The intima, a single layer of endothelial cells on a basal lamina; the media, a thick layer of elastic fibres, muscle cells and collagen contributing distensibility; the adventitia, a layer of collagen fibres contributing tensile strength. Acute aortic syndrome describes a series of life-threatening aortic pathologies, including aortic dissection, intramural haematoma and penetrating aortic ulcer (Fig. 35.1). [1] Incidence of acute aortic syndrome within the general population is 4 to 6 cases per 100,000 person-years, rising to 30 cases per 100,000 person-years in the population aged over 60. [2-4] Approximately 85%–95% of cases of acute aortic syndrome involve aortic dissection, with 5%–15% due to intramural haematoma and 5% due to penetrating aortic ulcer. [5]



The diagram presents three medical conditions that affect the stomach wall, arranged from left to right. The first condition, labelled dissection, depicts a separation within the stomach wall layers, which creates a split that extends vertically. The second condition, labelled penetration ulcer, depicts a deep erosion in the stomach wall that reaches the outer layer, which forms a crater-like structure. The third condition, labelled intramural hematoma, depicts a localised collection of blood within the stomach wall, which causes a bulge. Each condition is represented by a cross-sectional view of the stomach wall, with the affected areas highlighted to indicate the structural changes.

FIG. 35.1 Forms of acute aortic syndrome: dissection, penetrating aortic ulcer and intramural haematoma. (Reproduced from Elefteriades JA. Thoracic aortic aneurysm: reading the enemy's playbook. *Curr Probl Cardiol* . 2008;33:203-277.)

Classification of Acute Aortic Syndrome

Aortic Dissection

Aortic dissection occurs when the aortic wall is compromised by a tear in the intimal layer allowing passage of blood distally into the medial layer, creating a false lumen. Aortic dissection accounts for the majority of cases of acute aortic syndrome. The incidence of aortic dissection, both type A and type B, is higher in the male population with a rate in males of 5 per 100,000 person-years and 2 per 100,000 person-years in females. [2] Incidence correlates with age, with a mean age at presentation of 65, although patients tend to present at a younger age with type A versus type B. In patients with connective tissue disease or other significant predisposing factors presentation frequently occurs at younger ages and before the age of 40. [6]

The aorta withstands the force of ejection of cardiac output. With ageing there is loss of elasticity, increasing wall stress and risk of injury. This is accelerated by the presence of hypertension, particularly if poorly controlled. The ascending aorta experiences the highest dP/dT, the rate of rise in blood pressure. Intimal tears tend to be located here before propagating, usually antegrade although retrograde extension also occurs. The immediate impact of dissection is influenced by the progression of the false lumen. The false lumen may remain patent and blood may re-join the true lumen via a number of potential routes. An additional intimal fenestration may occur further down the aorta or the false lumen may thrombose. High pressure in the false lumen may lead to compression and reduced flow within the true lumen. Alternatively, the adventitial layer of the false lumen may rupture into other potential spaces such as the pericardium, pleural or peritoneal cavities, leading to exsanguination and death. As the dissection progresses it can extend to branches from the aorta leading to compromised flow and risk of ischaemia within cerebral, coronary, mesenteric, renal and limb vessels. [7]

Intramural Haematoma

Conditions causing cystic medial degeneration lead to reduction in the thickness and strength of the aortic wall and an increased risk of rupture of the vasovasorum. Bleeding into a diseased medial layer leads to formation of intramural haematoma (IMH), a crescentic thickening of the aortic wall. There is no evidence of intimal tear accounting for the presence of blood within the medial layer at the time of diagnosis, but up to a third of cases will progress to aortic dissection with rupture of the intimal layer as the lesion progresses. The haematoma can also progress outwards, resulting in rupture or formation of a pseudoaneurysm. Presenting features of aortic dissection and IMH are similar. Where aortic dissection affects males at a rate two to five times greater than females, IMH shows a more equal distribution, occurs in older patients and has a lower mortality than aortic dissection. IMH occurs more frequently within the descending aorta. [1,5]

Penetrating Atherosclerotic Ulcer

Penetrating atherosclerotic ulcers (PAU) of the aorta occur in patients with extensive atherosclerotic disease and are found more frequently within the descending aorta. They are characterised by an ulcerated lesion, potentially caused by rupture of an atheromatous plaque eroding through the internal elastic lamina of the aortic wall, leading to bleeding and haematoma formation within the medial layer. PAUs are usually localised. 40%–50% of lesions will progress either to rupture of the aorta or, less commonly, aortic dissection. [1]

Aortic Dissection

Classification of Aortic Dissection

Dissection is classified according to time from onset of symptoms to presentation and the anatomical location. Acute dissections were classically described as those presenting within 14 days of initial injury and chronic where the onset of symptoms exceeds this. Assessment of the International Registry of Aortic Dissection (IRAD) registry has more recently suggested a broader classification with hyperacute within 24 hours, acute within 7 days, subacute within 7 days to 1 month and chronic more than 1 month from symptom onset. Importantly, the highest mortality is in the acute phase, with an estimated 74% of deaths occurring within this time period.[8]

60% of dissections occur within the ascending aorta and 10% within the arch, with the remaining 30% located in the descending aorta.[9,10] The Stanford and DeBakey classifications of aortic dissection are additionally used according to the anatomical location of the abnormality, as the commonest sites of intimal tear are the regions just above the aortic valve and distal to the left subclavian artery[11,12] (Fig. 35.2).[13] Stanford type A dissections include any dissection affecting the ascending aorta, regardless of the severity of propagation. Stanford type B dissections affect only the aorta distal to the left subclavian artery. The DeBakey classification comprises three groups. Type I originates within the ascending aorta, extending into the arch and potentially the descending aorta. Type II originates and is limited to the ascending aorta. Type III is limited to the descending aorta only. In 2019 the European Association for Cardiothoracic Surgery and European Society for Vascular Surgery added a third category to the Stanford classification of non-A, non-B dissection, encompassing dissections arising from a flap within the aortic arch.[14]

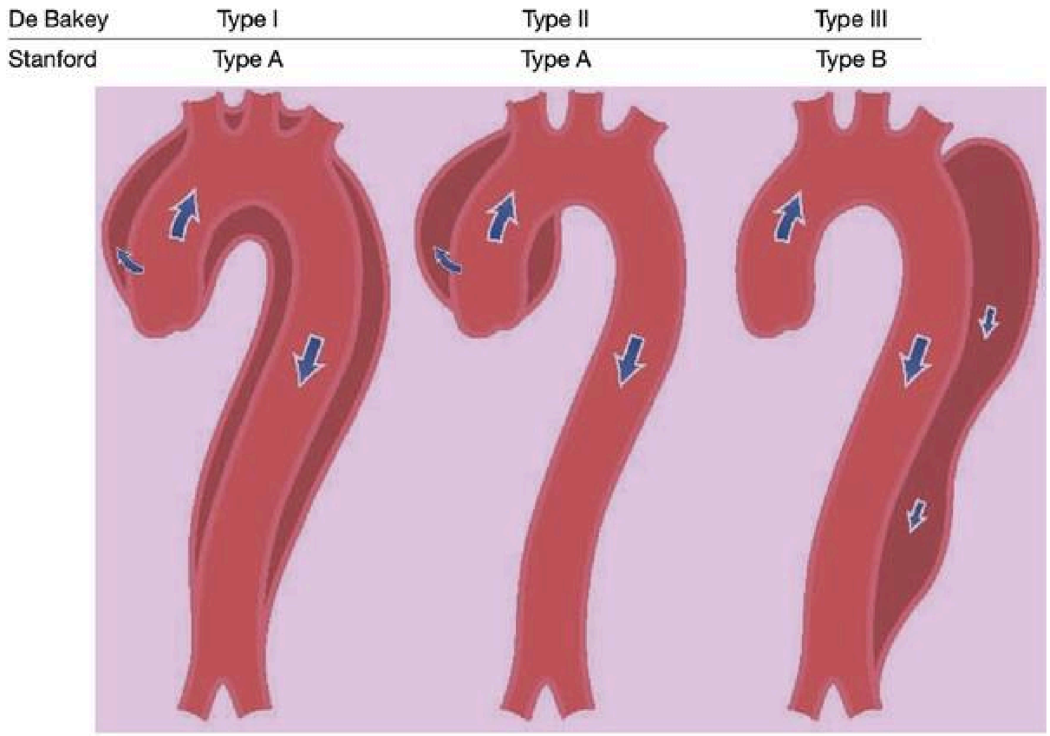


FIG. 35.2 DeBakey and Stanford classifications of aortic dissection. (Reproduced from Pepper J. Differential aspects of the disease and treatment of Thoracic Acute Aortic Dissection (TAAD) – the European experience. *Ann Cardiothorac Surg* . 2016;5(4):360-367.)

Aetiology of Aortic Dissection

Factors pre-disposing to aortic dissection are those impacting intimal and medial tissue quality (Box 35.1). Hypertension impacts the integrity of the intima with thickening and fibrosis, whilst thickening also impacts nutrient supply to the arterial wall. Loss of elasticity and reduced compliance further increase vulnerability of the vessel wall to damage. [7, 15] Hypertension is considered one of the most significant risk factors for aortic dissection, present in 80% of patients. Hypertensive patients have an incidence of aortic dissection of 21 per 100,000 person-years, versus 2 per 100,000 person-years in normotensive individuals. [10, 16] Connective tissue disorders lead to cystic medial degeneration and large vessel vasculitidies may also involve the aorta and increase the risk of dissection. Smoking is also associated with a significantly increased risk of dissection and aneurysm, with smokers demonstrating twice the incidence of dissection and thoracic aortic aneurysm, and five times the incidence of abdominal aortic aneurysm compared to non-smokers. [3] Patients with aortic aneurysm exhibit a progressive increase in the risk of aortic dissection as the aortic diameter increases. Where the diameter of the aorta exceeds 60 mm there is a 30% risk of related complications, including aortic dissection. [17] Aortic dilatation is not present in all situations of dissection, with 60% occurring in patients with an aorta measuring <55 mm. [18]

Box 35.1

Conditions pre-disposing to aortic dissection [7, 19, 20]

Hypertension
Age >65 years
Male gender
Smoking
Bicuspid aortic valve
Aortic hypoplasia or coarctation
Connective tissue disorder, e.g. Marfan syndrome, vascular Ehlers-Danlos syndrome and Loeys-Dietz syndrome
Inflammatory aortic disease, e.g. aortitis, giant cell arteritis, Takayasu arteritis, systemic lupus erythematosus and syphilis
Presence of aortic aneurysm
Turner's syndrome
Iatrogenic trauma – injury during cardiac catheterisation or surgery
Pregnancy – usually third trimester or early post-partum period
Cocaine use
Deceleration injury
Activity associated with intense isometric exercise, e.g. weightlifting, throwing and wrestling

Presentation

Aortic dissection presents with sudden onset of severe chest, back, abdominal or neck pain that may be described as sharp, stabbing, ripping or tearing in nature and may radiate to other sites. Pain is generally abrupt in onset, felt within the chest or back and is of greatest intensity at the time of onset, often described by the patient as the worst pain they have ever experienced. This is in contrast to the pain of a myocardial infarction which tends to progress as ischaemia evolves. Pain may be accompanied by cardiovascular compromise, with or without evidence of visceral ischaemia, and so the patient may present with collapse. Pain may have resolved by the time the patient presents for medical attention and so ascertaining an accurate history and description of the pain is essential. [21] Alternatively, pain may continue to be severe and resistant to treatment, often in conjunction with severe uncontrollable hypertension. [20]

Potential consequences of aortic dissection and associated clinical signs are shown in Table 35.1 . Malperfusion occurs when there is expansion of the false lumen combined with collapse of the true lumen due to elastic recoil, and thus cessation of blood flow via aortic branches at the level of the dissection. Assessment of the patient, both at presentation and throughout admission, should exclude the presence of these complications and this should be reviewed at regular intervals for evolution of symptoms so that management plans can be expedited when necessary. [7, 10] Visceral and renal ischaemia occur less frequently when the tear is located within the ascending aorta, and more frequently when it is located within the distal arch or descending aorta. [22, 23]

Table 35.1

Signs and symptoms of acute aortic syndrome

CLINICAL SIGNS AND SYMPTOMS	CAUSE
Asymmetric blood pressure (>20 mm Hg) between limbs	Compromise of branch artery flow
Bowel ischaemia or gastrointestinal bleed	Malperfusion of the coeliac or superior mesenteric artery
Dysphagia	Compression of the oesophagus
Dyspnoea	Compression of trachea or bronchus, congestive heart failure from aortic regurgitation or cardiac tamponade
Haemoptysis	Vascular rupture into lung parenchyma
Hoarseness	Compression recurrent laryngeal nerve
Horner’s syndrome	Compression of sympathetic chain
Myocardial ischaemia or myocardial infarction	Coronary artery involvement by dissection or compression by aneurysm
New murmur of aortic regurgitation	Incomplete aortic valve closure secondary to leaflet tethering by the dilated aorta, or cusp prolapse because of dissection into the aortic root or detachment of valve commissures from the aortic wall due to the dissection itself
Oliguria or haematuria (gross)	Malperfusion of one or both renal arteries

CLINICAL SIGNS AND SYMPTOMS	**CAUSE**
Paraplegia	Spinal malperfusion attributable to intercostal artery involvement
Lower extremity ischaemia	Malperfusion of iliac artery
Shock	Cardiac tamponade, haemothorax, frank aortic rupture, acute severe aortic regurgitation, severe myocardial ischaemia
Shortness of breath	Pericardial effusion, congestive heart failure from acute severe aortic regurgitation or haemothorax
Stroke symptoms, coma, altered conscious level	Carotid or vertebral artery involvement
Superior vena cava syndrome	Compression of the superior vena cava
Syncope	Carotid artery involvement or cardiac tamponade

Reproduced from Isselbacher EM, Preventza O, Black JH 3rd, et al. 2022 ACC/AHA guideline for the diagnosis and management of aortic disease: a report of the American Heart Association/American College of Cardiology Joint Committee on Clinical Practice Guidelines. *Circulation* . 2022;146:e334–e482.

Blood pressure should be assessed in both upper and lower limbs, with significant discrepancy indicating potential aortic pathology. The diastolic murmur of aortic regurgitation was reported in 44% of patients presenting with type A dissection and 12% presenting with type B. [10] Aortic regurgitation may occur due to aortic leaflet prolapse or distortion of closure of the valve by the dissection flap. After rupture, acute aortic regurgitation is the second highest cause of death in patients with aortic dissection, whereby patients present with rapid onset heart failure and cardiogenic shock. [24] The ejection systolic murmur of aortic stenosis may be present if the patient has a bicuspid aortic valve with associated narrowing.

Investigation

A high index of suspicion is required as initial investigations may be inconclusive. A contrast-enhanced computed tomography (CT) scan is the most widely used imaging modality as it can be performed swiftly and allows identification of the extent of the dissection, the size of the true and false lumen, involvement of arterial branches and the presence of haematoma. Arterial phase imaging is required and must include the entire aorta, iliac and femoral vessels. [25] Ideally, a gated scan performed with electrocardiogram (ECG) synchronisation will assist in the production of motion-free images of the aortic root. [21]

50% of patients may have radiographic signs of aortic dissection on chest x-ray (CXR) (Box 35.2). A 12-lead ECG may demonstrate non-specific ST or T wave changes which may include those mimicking myocardial infarction with ST elevation or the presence of new Q waves. The presence of ECG changes consistent with myocardial infarction has been shown to correlate with delayed diagnosis. [26]

Box 35.2

Chest x-ray abnormalities in aortic dissection [21]

Widened mediastinum >8 cm on a posterior-anterior (PA) film
Abnormal, blunted aortic knob
Ring sign – displacement of the aorta >5 mm past the calcified aortic intima
Pleural effusion
Pleural cap – fluid in the apex of the hemi-thorax

Deviation of the trachea and left main bronchus

Utility of blood tests can be limited. D-dimer, if less than 500 ng/mL at 24 hours from onset in low-risk patients, is associated with a low probability of dissection but is not helpful in the acute presentation. [27] 50% of patients with aortic dissection have elevated levels of troponin T. As with ECG changes, elevation in troponin T can be associated with delayed diagnosis and development of inappropriate management plans. [28] Evidence of malperfusion may initially be subtle. Raised serum creatinine, bilirubin, amylase or hepatic enzymes may be an initial indication of evolving malperfusion and clinicians should be alert for new clinical signs. [29]

Transthoracic echocardiography (TTE) allows imaging of some aortic segments, the aortic root and proximal ascending aorta, but due to low sensitivity a negative TTE cannot rule out aortic dissection. Transoesophageal echocardiography (TOE) may be helpful in the acute setting in patients with haemodynamic instability but is dependent upon availability of suitably trained and experienced operators, requires sedation or general anaesthesia and provides limited views of the distal aortic arch and proximal descending aorta due to anatomical obstructions. The aortic root and descending aorta can usually be visualised, where a dissection flap (Fig. 35.3) or false lumen (Fig. 35.4) may be identifiable, although this is dependent upon the quality and orientation of the sonographic view obtained. Echocardiography may also demonstrate pericardial collection, evidence of features of tamponade, aortic regurgitation or regional wall motion abnormalities.

Magnetic resonance imaging (MRI) is rarely used in acute presentation due to lack of availability, time delay, challenges with monitoring during imaging and the presence of implanted metal devices, [19] but it may be employed during the follow-up period.

Recommendations from the European Society of Cardiology (ESC) suggest consideration of presence of pre-disposing conditions, pain features and clinical examination when planning the investigative approach. Table 35.2 summarises the diagnostic methods with their relative advantages and disadvantages. A risk scoring approach, the Acute Aortic Dissection Risk Score (AAD-RS), using parameters as shown in Table 35.3 , has been advocated as part of a diagnostic algorithm such as that shown in Fig. 35.5 . In patients with a low probability of dissection, the diagnostic approach should begin with an assessment of D-dimer, TTE and CXR, as this combination of tests has a combined diagnostic value and may yield alternative diagnoses. In patients with a high probability of dissection or inconclusive TTE, contrast-enhanced CT is recommended.

Table 35.2

Diagnostic methods in aortic dissection

DIAGNOSTIC METHOD	ADVANTAGES	DISADVANTAGES
D-dimer measurement	Fast and easily accessible Very high sensitivity of 97%	Poor specificity of 56%
Chest x-ray	Fast and non-invasive	Low sensitivity and specificity
TTE	Rapid and non-invasive	Restricted in patients with abnormal chest wall, obesity, pulmonary emphysema and mechanical ventilation. Not all aortic segments can be visualised
TOE	Overcomes limitations of TTE Suitable for haemodynamically unstable patients Excellent sensitivity of 95% and specificity of 95% Evaluation of aortic incompetence and pericardial effusion	Semi-invasive and requires sedation and blood pressure control. Not feasible in patients with oesophageal disease Tends to be observer and experience dependent. Not all aortic segments can be visualised

DIAGNOSTIC METHOD	ADVANTAGES	DISADVANTAGES
Contrast-enhanced CT	Fast image acquisition Possibility of 3D images of entire aorta Excellent sensitivity of 100% and specificity of 98%	Exposure to ionising radiation and contrast agents
MRI	Excellent sensitivity of 98% and specificity of 98% Visualisation of the entire aorta	Incompatible with implanted metal devices and pacemakers Problematic patient monitoring during examination Lack of widespread availability in the emergency setting

The flowchart shows the evaluation and management of acute chest pain, based on medical history and clinical examination. At the top, the process begins with acute chest pain, which branches into two categories, unstable and stable. They depend on haemodynamic stability in accordance to European Society of Cardiology guidelines. The unstable path leads to Transesophageal Echocardiogram or Computed Tomography Scan, followed by Aortic Dissection Study, with a note to consider Aortic Dissection Study for atypical symptoms. The stable path divides into low probability with a score less than one and high probability with a score greater than or equal to two. The low probability path leads to D dimer tests. If D dimer is negative, no further tests occur. If D dimer is positive, Transesophageal Echocardiogram or Computed Tomography Scan occurs, followed by a widened mediastinum on chest X ray, which leads to a definitive diagnosis or referral to a surgical team and pre surgical Transesophageal Echocardiogram. The high probability path leads directly to Transesophageal Echocardiogram or Computed Tomography Scan. If inconclusive, an Aortic Dissection Study occurs. If confirmed, a diagnosis of aortic dissection or intramural hematoma results. A note at the bottom left indicates unstable haemodynamic states include persistent chest pain, hypotension, shock, or neurological deficits.

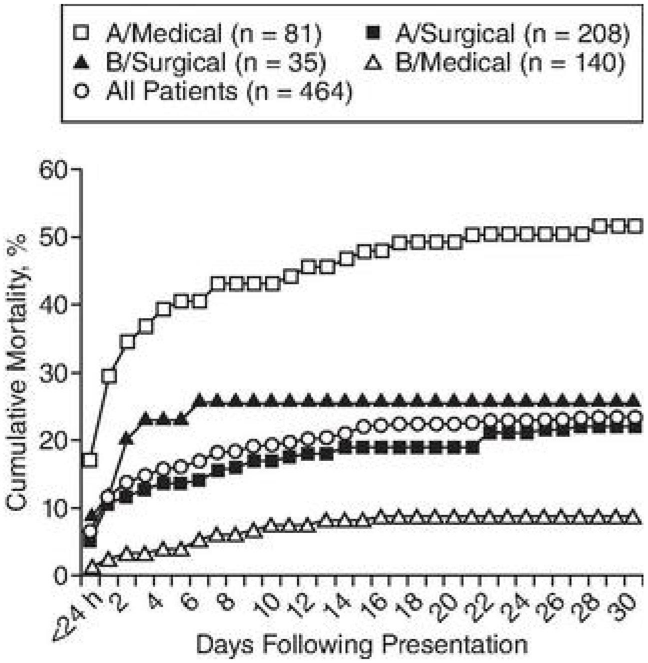
Management of Acute Aortic Syndrome

Management of aortic dissection requires rapid assessment, diagnosis and intervention. The UK National Health Service (NHS) Acute Aortic Dissection Toolkit [30] describes the key principles to support a reduction in morbidity and mortality associated with aortic dissection. Management plans and associated urgency are influenced significantly by the location of the dissection. At the point of diagnosis, the patient should be discussed urgently with specialist services via local pathways. Thirty-day mortality according to location and strategy used from the IRAD study are shown in Fig. 35.6 .



The graph presents cumulative mortality rates over a period of thirty days following presentation for patients with aortic dissections. The horizontal axis represents days that follow the presentation, which ranges from zero to thirty in increments of two. The vertical axis represents cumulative mortality in percentage, which ranges from zero to sixty in increments of ten. Three groups of patients appear in the graph. The first group, labelled Type A Medical, includes eighty one patients. The second group, labelled Type A Surgical, includes two hundred eight patients. The third group, labelled All Patients, includes four hundred sixty four patients. The Type A Medical group reaches the highest mortality rate, which approaches fifty percent by day thirty. The Type A Surgical group reaches a mortality rate of around thirty percent by day thirty. The All Patients group falls between the two, with a mortality rate of approximately forty percent by day thirty.

FIG. 35.6 Thirty-day mortality by dissection type and management. (Reproduced from Hagan PG, Nienaber CA, Isselbacher EM, et al. The International Registry of Acute Aortic Dissection (IRAD): new insights into an old disease. *JAMA* . 2000;283:897-903.)

Initial Medical Management of Acute Aortic Syndrome

Regardless of the location of the dissection, initial medical management must urgently decrease aortic wall stress and reduce the risk of further extension or rupture whilst definitive plans for further assessment and intervention are made. Best practice is for the patient to be transferred to a level 2 or 3 critical care setting with invasive blood pressure monitoring. First-line treatment frequently involves intravenous beta-blockade due to onset time and the ability to titrate easily. Labetalol, metoprolol or esmolol are frequently administered with a target systolic blood pressure below 120 mm Hg, or as low as tolerated without evidence of end-organ hypoperfusion, and heart rate of 60 to 80 bpm. Where there are contraindications to the use of beta-blockers such as asthma or heart failure, the use of esmolol is felt to be a reasonable first choice due to its short half-life. Alternatively, an intravenous non-dihydropyridine calcium channel blocker such as verapamil or diltiazem may be considered.[21, 31]

Where beta-blockers alone are insufficient, the use of vasodilators such as glyceryl trinitrate as a second-line treatment is recommended, although always in addition to and after commencement of a beta-blocker to avoid reflex tachycardia with a consequential increase in the force of left ventricular contraction and thus wall stress. In cases of severe hypertension sodium nitroprusside in addition to beta-blockade should be considered.[31] Opiate-based analgesia will also likely be required, improving both pain control and achievement of favourable haemodynamic parameters. The above treatments should be instituted as soon as possible as definitive management may require transfer of the patient to another centre.[31, 24]

Management of Type A Aortic Dissection

Type A dissection is associated with a high early mortality, up to 1% to 2% per hour after symptom onset,[32] secondary to aortic rupture, extension into the pericardium causing tamponade, visceral ischaemia or acute heart failure as a consequence of severe aortic regurgitation. It has been estimated that 21% of patients die before treatment in a hospital[33] and overall, 25% of patients die within 24 hours, 50% within 48 hours and 75% within 2 weeks if untreated.[13,34] Features associated with increased mortality include previous aortic valve replacement, migrating chest pain, pre-operative limb ischaemia, hypotension at presentation and the presence of shock with or without cardiac tamponade.[10]

Cardiac tamponade in a patient with aortic dissection may develop and present in two different ways. A pericardial collection may evolve gradually due to continuous transudation through the suddenly more permeable aortic wall in up to 40% of cases, where recognised allowing emergent transfer to theatre. Alternatively in 6%–10% of cases, frank rupture with haemorrhage into the pericardial space may occur, associated with cardiac arrest.[20] Where cardiac arrest occurs in an aortic surgical centre, salvage surgery may be considered, although the mortality in this context is high.

Treatment of type A dissection will almost always involve a surgical approach. Surgery involves graft replacement of the affected portion of the ascending aorta (and aortic root or arch as required) with the aim of restoring true lumen flow, resolving associated ischaemia and correcting acute aortic regurgitation, if present. Aortic valve replacement may be performed if resolution of competency of the valve is not anticipated. 87%–90% of type A dissections are managed surgically according to a recent registry study and the in-hospital mortality for those undergoing surgical repair is approximately 18%[10,34] although this is reported to be as low as 5%–8% in specialist centres. In patients where the operative risk is deemed too high, a medical management approach may be adopted, but this is associated with high mortality of 57%[10] (Fig. 35.7A). Whilst advancing age is associated with increased mortality, elderly patients do still benefit from surgery with better outcomes in the short and medium term than medical management alone.[35,36] For frail patients with significant contraindications to surgery, an individualised risk:benefit decision and discussion with the patient may lead to a medical management strategy.

The graph presents two Kaplan-Meier survival curves for patients with aortic dissections, divided into two sections labelled A and B. Section A focuses on Dissection Type A, and Section B focuses on Dissection Type B. Each section has a graph with the horizontal axis labelled time from symptom onset in days, which ranges from zero to thirty in increments of five. The vertical axis represents survival probability, which ranges from zero point seven to one point zero in increments of zero point one. In Section A, two lines compare outcomes. The line labelled surgical management starts at one point zero and gradually descends to around zero point eight by day thirty. The line labelled medical management starts at one point zero and descends more steeply to around zero point five by day thirty. A label notes Log rank Chi square probability less than zero point zero one. In Section B, two lines also compare outcomes. The line labelled surgical management starts at one point zero and descends to around zero point nine by day thirty. The line labelled medical management starts at one point zero and descends to around zero point eight five by day thirty. A label notes Log rank Chi square probability less than zero point zero one.

Surgical replacement options are shown in Figs. 35.8 and 35.9 . All involve open replacement of the ascending aorta and depending on extent also the aortic root, hemi-arch or arch.

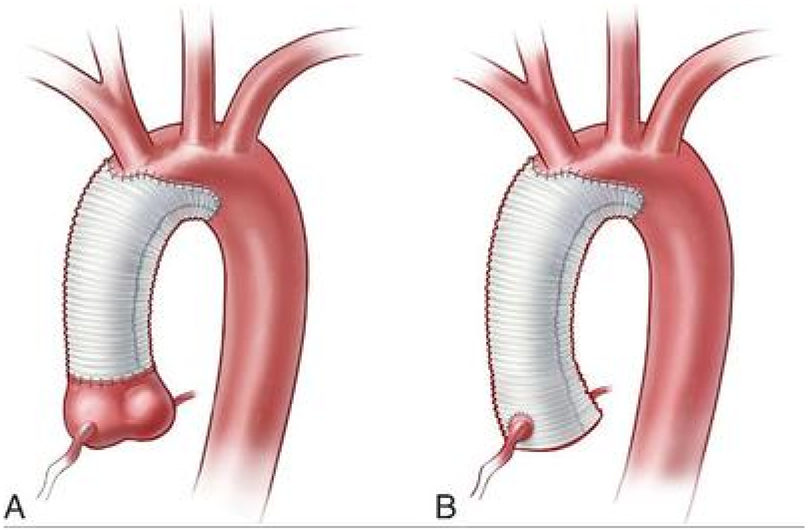

FIG. 35.8 Surgical approaches in the management of aortic dissection. (A) Ascending aorta and hemiarch replacement; (B) Root, ascending and hemiarch replacement (Reproduced partially from Heuts S, Schalla S, Ramaekers MJFG, et al. Imaging surveillance for complications after primary surgery for type A aortic dissection. *Heart* . 2023;109:96–101.)

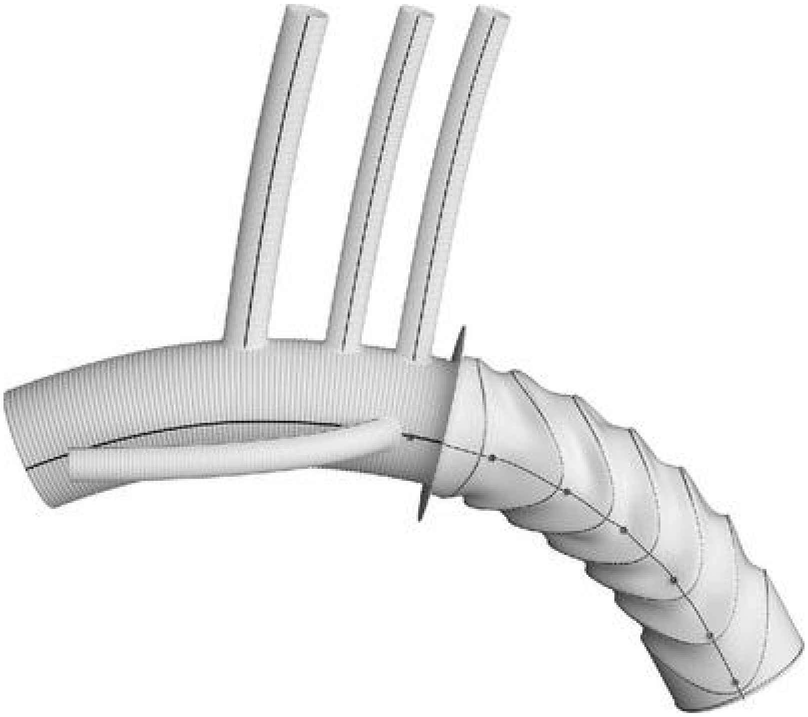

FIG. 35.9 Aortic arch replacement with Terumo Thoraflex Hybrid frozen elephant trunk graft.

Where disease is not limited to the ascending aorta and aortic arch, an elephant trunk graft may be utilised. An elephant trunk graft extends beyond the distal anastomosis of the aortic arch, into the proximal descending aorta, and may be described as either frozen or floppy. A frozen elephant trunk graft is a hybrid prosthesis, consisting of a stent that can be inserted in an antegrade direction into the descending aorta with a proximal surgical graft used to replace the aortic arch. A floppy elephant trunk is a surgical graft implanted such that a short section of graft projects into the descending aorta.

The choice of graft is dictated by a number of factors but chiefly the presence of concomitant disease of the descending aorta that may require further surgery. A floppy elephant trunk provides an anastomotic site for suturing a further graft during elective open surgery. A frozen elephant trunk creates a landing zone for a future second-stage endovascular approach if anatomy is favourable and would allow this approach to be possible. Where an intimal tear is noted within the arch or proximal descending aorta a frozen elephant trunk graft may also result in exclusion of the tear, thus stabilising the dissected descending aorta and potentially reversing malperfusion. The surgery performed must be noted by the intensive care team on admission to critical care post-operatively, to understand the spectrum of complications that may develop.

Endovascular intervention for type A dissection is limited by the short landing zone of the aortic root, presence of the coronary ostia and distance from the aortic valve. Whilst an emerging area of interest and development, routine practice involves open surgical repair although this may present future options. [20]

Management of Type B Aortic Dissection

An interdisciplinary consensus statement regarding type B dissection states that management of uncomplicated disease is predominantly medical, focusing on blood pressure control. Patients managed medically have the lowest estimated mortality between 6.4% and 10%.

Medical Management of Type B Dissection

Most patients with type B dissection have a background of hypertension and in the acute phase of acute aortic syndrome blood pressure may be further elevated. The mainstay of treatment in uncomplicated type B dissection is therefore the use of anti-hypertensive medications, as described, along with pain management.

As per advice in the NHS Aortic Dissection Toolkit, uncomplicated type B dissection may be managed at the admitting hospital without transfer to a specialist centre, but ongoing co-ordinated support from a specialist multi-disciplinary team is essential. Uncomplicated disease may progress and become complicated despite medical treatment and so triggers for transfer and plans for re-imaging should be clearly agreed. [30] Where there is pain or hypertension refractory to medical management, intervention may be required at a time earlier than initially planned. Consensus advice is that imaging should be performed at admission, 7 days, prior to discharge from the hospital and at 6 weeks. [29] In patients with chronic disease, 5-year survival has been estimated as only 60% to 80%. Ongoing assessment for evolution of disease and intervention when indicated is essential. [10, 29, 31]

Endovascular Management of Type B Dissection

The incidence of aortic rupture following type B dissection is lower than that of type A dissection, but rupture still represents the highest cause of death followed by malperfusion. [37] Type B dissection is classified as complicated in the presence of malperfusion with evidence of evolving organ failure, persistent hypertension despite best medical therapy or increases in peri-aortic haematoma or haemorrhagic pleural effusion on serial CT scans suggesting impending rupture. [31] IRAD data suggests approximately 25% of patients presenting with type B dissection should be classified as complicated [38] and 25%–50% of patients with acute type B aortic dissection managed medically will go on to develop aneurysmal degeneration of the affected aorta requiring endovascular or open repair as the disease progresses. [39]

Where medical management is insufficient, endovascular intervention with thoracic endovascular aortic repair (TEVAR) may be required. Endovascular intervention in the early phase is associated with a mortality of 10.2%. [10], [29] Endovascular intervention is preferred if possible and is associated with significantly better survival rates than open surgical intervention (Fig. 35.7B). The aim of endovascular intervention is to restore flow within the true lumen, stabilise an aneurysm if present and prevent rupture.

The INSTEAD trial randomised patients with subacute or chronic type B dissection to either best medical management or TEVAR and demonstrated an improved 5-year aorta-specific mortality in the TEVAR group compared to best medical management (6.9% vs. 19.3%, $P = .04$). [39] In patients presenting later in the disease process, the decision of how best to manage them in the absence of complicated disease may be more nuanced.

Surgical Management of Type B Dissection

Where endovascular treatment of chronic type B dissection is not feasible due to anatomical constraints, history of connective tissue disease or previous surgery, open surgery or a hybrid approach is considered. Urgent or emergent surgery is rarely considered unless there is a concern of impending rupture, aorto-oesophageal fistula, contained rupture or iliofemoral malperfusion [40] but is associated with a high mortality of 25% to 50%. [10] , [41]

Management of IMH and PAU

Management of patients with IMH and PAU have classically followed management advice for dissection within the same region of the aorta.

ACC/AHA guidance advises patients with type A IMH or PAU to undergo prompt open surgical repair. 18% present already with features of rupture and have a 100% mortality without surgical intervention. In patients with significant co-morbidities considered higher risk for surgical intervention and where there are no high-risk imaging features, a period of initial medical management may be considered. [31] Medical management is associated with a 40% mortality and so should be reserved for stable patients at highest risk, and shared decision making with the patient regarding the management approach is essential.

Mortality following both type B IMH and PAU is lower than that of dissection. Treatment strategies for type B IMH may involve either medical management or TEVAR, as per guidance for type B dissection, with an overall 30-day mortality of 3.6% or 4.1% respectively in uncomplicated cases. In patients with complicated type B IMH, mortality for open surgery was 16% in one study, compared to 4.6% in the TEVAR group. [42] TEVAR in type B IMH is associated with positive aortic remodelling, significant true lumen expansion, IMH resolution and a decrease in aortic diameter. [43] As a result, many centres may choose to perform TEVAR even in the absence of features of complicated disease, although assessment of individual cases clinically and radiologically is essential.

Intensive Care Management of Acute Aortic Syndrome

Pre-Operative Considerations

Patients with confirmed aortic dissection require rapid referral to the appropriate surgical team and potentially transfer to a specialist centre. As per the NHS Acute Aortic Dissection Toolkit, all patients with type A or complicated type B dissection should be managed in appropriate level 2 or 3 area. Transfer, where required, should be undertaken by the adult critical care transfer service for the region that the patient is in or where not available should be facilitated by a hospital team with appropriate training and education in critical care transfers to escort the patient. [30] Management of pain and treatment of hypertension as described, ideally with invasive blood pressure monitoring, should be initiated as soon as possible after diagnosis.

In preparation for future surgical intervention in type A dissection monitoring of right radial arterial blood pressure, along with femoral arterial blood pressure, is required to allow monitoring of blood pressure on both sides of the aortic arch peri-operatively for detection of cerebral malperfusion. Where axillary cannulation is planned additional left radial monitoring may be considered and therefore a discussion with the surgical team regarding the anticipated approach to surgery should take place. Large bore intravenous access and insertion of a central venous catheter for monitoring and administration of medication peri-operatively will also avoid delays following transfer to the operating theatre where intervention is planned.

Post-Operative Considerations

Communication between the surgical and critical care teams in the post-operative period is essential. A clear understanding of the surgery performed including the extent of graft coverage, haemodynamic disturbance, whether planned or unplanned concomitant procedures were required, and any concerns regarding malperfusion and the haemodynamic parameters to be targeted should be clearly documented. [44]

Complications of surgery involving the aortic root, ascending or arch include those occurring following general cardiac surgery, but with additional procedure-specific risks that have implications for post-operative management.

Neurological Complications

Neurological assessment should be performed as soon as post-operative stability and freedom from bleeding are confirmed. Sedation strategies may involve infusions of propofol and an opiate such as morphine or alfentanil, with increasing use of agents such as dexmedetomidine. Where there is evidence of a new neurological deficit, immediate CT imaging of the brain and aorta should be performed to allow identification of haemorrhagic pathology requiring neurosurgical intervention or issues with the implanted graft. [44] Embolic strokes may occur secondary to atherosclerotic debris disturbed during surgery or microemboli of air. Management is usually conservative due to the lack of an onset time allowing consideration of embolectomy. Mortality in patients suffering peri-operative stroke is significantly increased. Data reported by the Nordic Consortium for type A thoracic aortic dissection described a 30-day mortality of 27.1% for patients with stroke versus 13.6% in patients without, and a 5-year mortality of 42.9% in patients with stroke versus 25.6% in patients without. [45]

Spinal Cord Protection

The spinal cord receives blood from multiple sources according to the level. The subclavian arteries supply vertebral arteries and in turn the anterior spinal artery. Posterior intercostal arteries supply spinal segmental arteries within the mid-thoracic region. A large segmental artery, the Artery of Adamkiewicz, branches from the left side of the descending aorta and also supplies the anterior spinal artery within a large area of the thoracolumbar spinal cord. Branches from the internal iliac arteries supply the lumbosacral spinal cord. [46]

Surgery involving the descending aorta, both open and endovascular, may compromise the blood supply to the spinal cord. Endovascular stenting of the descending aorta is associated with a risk of spinal cord ischaemia if important intercostal vessels are covered, and where large intercostal vessels are identified a shorter length of stent may be considered if feasible. During treatment of a type A dissection, frozen elephant trunks are associated with a small but significant risk of paraplegia due to occlusion of intercostals either directly or due to thrombosis in a false lumen. In addition, frozen elephant trunk grafts have been associated with clot formation at the distal end, which can result in embolisation with significant associated morbidity and mortality. Floppy elephant trunk grafts do not carry these risks.

Use of Spinal Drains

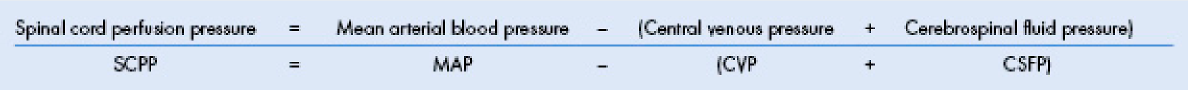
Spinal drains are employed according to the perceived risk of spinal cord injury, generally relating to the proportion and location of surgical replacement of the aorta. In endovascular surgery, risk factors for spinal cord ischaemia and therefore indications for placement of a spinal drain include planned extensive coverage of the descending aorta, patients with previous abdominal aortic surgery (both open and endovascular) and those with specific anatomical concerns such as severe atherosclerosis of the thoracic aorta, occlusion of the left subclavian artery or hypogastric arteries and more extensive coverage of the thoracic aorta by the graft. [44]

In the emergency setting, spinal drains are rarely sited prior to surgery due to the urgency of the situation. In all patients undergoing intervention to the descending aorta, regular assessment of neurology must be performed in the post-intervention period, either by lightening sedation or with the use of motor-evoked potentials. Where there is development of a new focal neurological deficit following aortic surgery, the surgical and critical care teams should be alerted immediately. Development of new neurological signs should be classed as an emergency and will require urgent contrast CT imaging of the brain and contrast CT imaging of the aorta. [6] Measures to optimise spinal cord oxygen delivery should be undertaken and where a spinal drain is not already in situ one may be sited.

The presence of a spinal drain allows measurement and augmentation of CSF pressure to optimise spinal cord perfusion (Box 35.3). The majority of centres will maintain a spinal cord perfusion pressure (SCPP) of 70 mm Hg in patients with stable neurology. Blood pressure targets contrast with those pre-operatively with a target mean arterial blood pressure of 80 to 90 mm Hg. Cerebrospinal fluid pressure (CSFP) should be maintained at 10–15 mm Hg and should be continually monitored with cautious drainage of fluid at a rate not exceeding 10–20 mL/h, if required. The minimum volume of cerebrospinal fluid (CSF) should be drained to achieve the target SCPP. Where it is not possible to achieve a CSFP below 15 mm Hg the MAP target should be increased accordingly to maintain an adequate SCPP. [43] Other steps to improve spinal cord oxygen delivery include maintenance of Hb > 100 g/L.

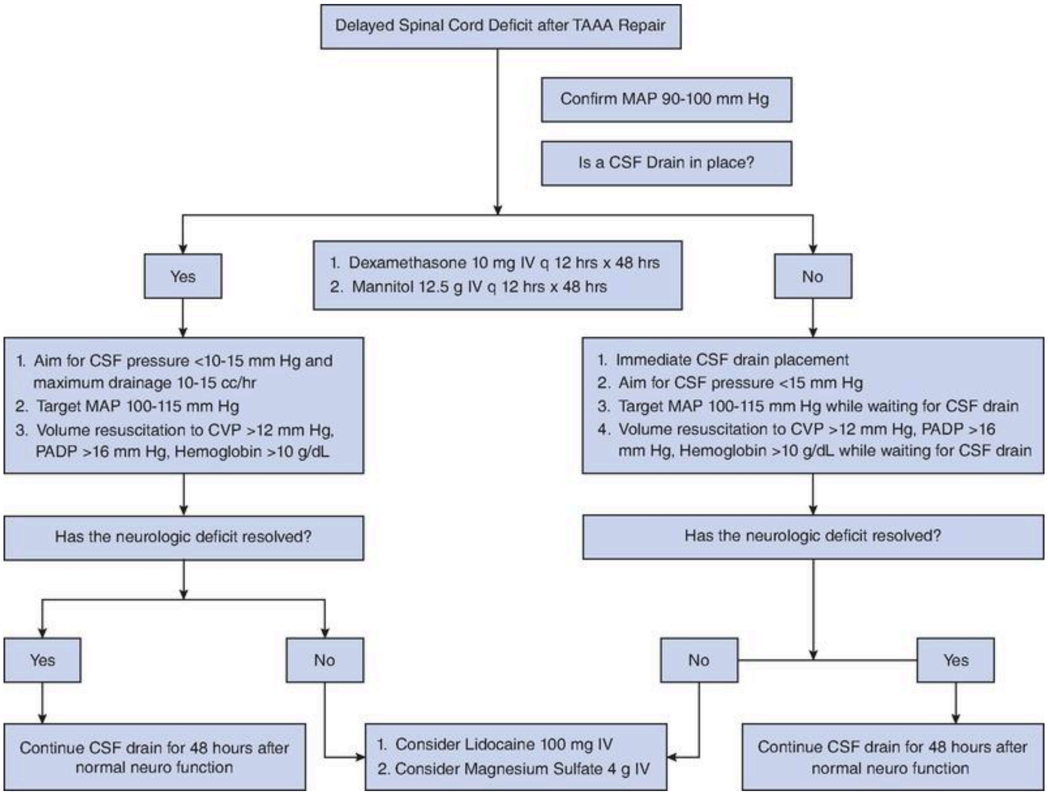
Box 35.3

Factors influencing spinal cord perfusion pressure



Spinal cord perfusion pressure	=	Mean arterial blood pressure	−	(Central venous pressure	+	Cerebrospinal fluid pressure)
SCPP	=	MAP	−	(CVP	+	CSFP)

With onset of new neurological signs, a series of interventions (Fig. 35.10), sometimes referred to as the COPS protocol, may be instituted. COPS is an acronym for **C** SF drain status, **O** ptimisation of oxygen delivery and **P** atient **S** tatus optimisation regarding SCPP, MAP and cognitive status. [47] Vasopressors should be titrated to achieve a MAP target of 90 to 100 mm Hg and drainage of CSF should be performed to target a lower CSF pressure of 10 to 12 mm Hg. Inspired fraction of oxygen should be increased and the patient should maintain a haemoglobin concentration greater than 120 g/L, receiving red blood cell transfusion where the measurement is lower than this.



Delayed Spinal Cord Deficit after TAAA Repair
Confirm MAP 90-100 mm Hg
Is a CSF Drain in place?
Yes
1. Dexamethasone 10 mg IV q 12 hrs x 48 hrs
2. Mannitol 12.5 g IV q 12 hrs x 48 hrs
No
1. Aim for CSF pressure <10-15 mm Hg and maximum drainage 10-15 cc/hr
2. Target MAP 100-115 mm Hg
3. Volume resuscitation to CVP >12 mm Hg, PADP >16 mm Hg, Hemoglobin >10 g/dL
1. Immediate CSF drain placement
2. Aim for CSF pressure <15 mm Hg
3. Target MAP 100-115 mm Hg while waiting for CSF drain
4. Volume resuscitation to CVP >12 mm Hg, PADP >16 mm Hg, Hemoglobin >10 g/dL while waiting for CSF drain
Has the neurologic deficit resolved?
Has the neurologic deficit resolved?
Yes
No
No
Yes
Continue CSF drain for 48 hours after normal neuro function
1. Consider Lidocaine 100 mg IV
2. Consider Magnesium Sulfate 4 g IV
Continue CSF drain for 48 hours after normal neuro function

The flowchart presents a medical protocol for delayed spinal cord deficit after thoracic aortic aneurysm repair. At the top, the process begins with a delayed spinal cord deficit after thoracic aortic aneurysm repair. The first step confirms mean arterial pressure between ninety and one hundred millimetres of mercury and checks if a cerebrospinal fluid drain is in place. If yes, three actions occur. First, aim for cerebrospinal fluid pressure below ten centimetres of water and mean arterial pressure above ninety millimetres of mercury. Second, administer dexamethasone at ten milligrams intravenously, followed by four milligrams every six hours. Third, maintain target mean arterial pressure between one hundred and one hundred fifteen millimetres of mercury, cerebrospinal fluid pressure below ten centimetres of water, and hemoglobin above ten grams per deciliter, and wait for cerebrospinal fluid drain removal. If no cerebrospinal fluid drain exists, the protocol checks if the neurological deficit resolves. If yes, the process ends with a cerebrospinal fluid drain for at least forty eight hours after normal neurological function returns. If no, two steps follow. First, consider lidocaine at one hundred milligrams intravenously. Second, consider magnesium sulfate at four grams intravenously. The flowchart includes decision points to assess if the neurological deficit resolves at each stage, which guide the next steps accordingly.

FIG. 35.10 Management strategy for delayed spinal cord deficit following surgery to the descending aorta. This refers to delayed spinal cord deficit after thoracoabdominal aortic aneurysm repair (TAAA), but the process applies to all patients undergoing intervention to the descending aorta. (Reproduced from Chatterjee S, Preventza O, Orozco-Sevilla V, Coselli JS. Perioperative management of patients undergoing thoracic endovascular repair. *Ann Cardiothorac Surg* . 2021;10(6):768-777.)

Where there is no improvement in the neurological status of the patient, a higher MAP of 100 to 115 mm Hg can be targeted to maximise the change of recovery. Multiple adjunctive agents have been considered to try to aid recovery including intravenous use of dexamethasone, mannitol, acetazolamide, magnesium sulphate and lidocaine. The evidence for all is limited but with an associated perceived low risk of harm. Where paraplegia has persisted for over 48 hours, it is likely to be permanent. [44]

Removal of the drain is usually considered at 48 to 72 hours post-operatively. The drain may be clamped and drainage stopped for 6 to 24 hours prior to removal where there is no suggestion of new neurological deficit. Local practices and policies should be followed regarding use of heparin or low molecular weight heparin for venous thromboprophylaxis and management of spinal drain removal.

Complications of spinal drain insertion and CSF drainage include dural puncture headache, intracranial and subarachnoid haemorrhage, epidural haematoma, meningitis and spinal cord abscess. If CSF becomes blood stained at any stage all drainage should stop, coagulopathy should be reversed if present and consideration should be given to urgent CT imaging of the brain and spinal cord to exclude intracranial haemorrhage. [48]

Cardiovascular Complications

Surgery involving the aortic root will require reimplantation of the coronary arteries to the graft. The presence of ECG signs of myocardial ischaemia should prompt swift assessment of the cardiovascular status of the patient. TTE and TOE assessment should be performed to look for the development of new regional wall motion abnormality and, if present, coronary angiography should be considered as an emergency.

Respiratory Complications

A whole-body systemic inflammatory response in response to surgery contributes to the development of acute lung injury. Cardiac failure as a result of pre-operative aortic regurgitation or post-bypass myocardial dysfunction may contribute to the development of pulmonary oedema. In patients undergoing open surgery to the descending aorta, one-lung ventilation with retraction of the left lung for surgical access leads to significant pulmonary contusions and potentially bleeding from the lung, exacerbated further by coagulopathy. Focussed management of coagulopathy with use of point-of-care testing to guide product usage and lung protective ventilation throughout the peri-operative period is essential. Bronchoscopy, with or without bronchoalveolar lavage, may be required in the post-operative period where focal left-sided CXR signs of lobar collapse are caused by the presence of residual blood or thick secretions in the left main bronchus.

Hypothermia

Surgery to the aortic arch will require a period of deep hypothermic circulatory arrest. The patient is restored to normothermia via monitoring of core temperature via a bladder catheter temperature probe, but the deleterious effects may persist including shivering and rise in oxygen consumption and coagulopathy. Re-warming may therefore continue in the intensive care unit post-operatively with forced-air warmers and warmed IV fluids.

Vascular Complications

In patients undergoing TEVAR the incidence of major vascular complications is approximately 12%. Monitoring for evidence of evolving compartment syndrome or for ischaemic complications due to graft or arterial thrombosis, aortic dissection or endograft malpositioning is essential. [44]

The landing zone of an endovascular graft represents an area of a blood vessel of favourable anatomy and morphological characteristics into which the stent can be seated, creating an adequate seal to obliterate the diseased portion of the vessel beyond that point so that there is flow within the stent lumen only. Where the proximal landing zone of the endovascular graft is near the left subclavian artery flow may be compromised leading to arm or spinal cord ischaemia. Left subclavian to carotid bypass may be necessary to manage this and, in some circumstances, this will be performed prior to stenting where the risk of occlusion of the left subclavian artery is deemed to be high. [49] Early causes of mortality following TEVAR are aortic rupture and retrograde type A dissection. [50]

Distal stent graft-induced new entry (dSINE) is a rare complication of endovascular intervention resulting in a new intimal tear caused by the stent itself, rather than progression of the disease. To ensure adequate seating of the endovascular graft to reduce the risk of stent migration and adequate obliteration of the false lumen to prevent propagation of the false lumen, a degree of oversizing of the stent graft by 10% at the proximal landing zone is accepted practice. Where the anatomy of the aorta is such that this is associated with greater oversizing at the distal end of the graft the shear strain between the stent and aortic wall may lead to formation of a new intimal tear. dSINE may be an incidental finding identified during post-operative imaging of the aorta or may present more acutely with further signs of type B dissection relating to the affected portion of the descending aorta as already described. Medical management with blood pressure control is preferred as the first line. Re-intervention with a further endovascular procedure may be required where there is evidence of growth, contained rupture or malperfusion. [51]

Gastrointestinal Complications

Stress ulcer prophylaxis should be considered in line with local practices. Early enteral feeding should be the target in all patients, although malabsorption and ileus in the post-operative period can be problematic. The risk of malperfusion of the abdominal viscera should not be underestimated, either as a result of intra-operative hypotension, residual dissection or thrombosis within branch vessels. A low threshold for CT assessment should exist in the presence of bloody diarrhoea, abdominal pain and distension, high nasogastric tube aspirates or refractory lactic acidosis. Exploratory laparotomy may be required.

Post-Implantation Syndrome

13% to 60% of patients develop post-implantation syndrome, a series of features specific to endovascular treatment comprising fever, leucocytosis and elevated inflammatory markers. This is thought to be an immune-mediated inflammatory response. Age under 60 and operation time exceeding 3 hours were associated with an increased incidence of pyrexia and a greater immune response in younger patients. Patients in this cohort tended to have a longer hospital stay but without impact on mid- or long-term prognosis. [52] In all patients presenting with pyrexia, steps should be taken to assess for and exclude bacteraemia and evidence of infective foci, but in their absence, a diagnosis of non-infective pyrexia can be made. Treatment is supportive with no evidence that treatment with antibiotics is beneficial. [53]

Renal Complications

Acute kidney injury (AKI), with or without the requirement for renal replacement therapy is common after major aortic intervention. The incidence of AKI following TEVAR is 10%, compared to 5%–29% in open surgery with 4%–17% requiring renal replacement therapy.[53],[54] Pre-operative dissection involving the renal artery, intra-operative renal ischaemia or injury and large-volume transfusion may all contribute to this risk. The risk following TEVAR is exacerbated in cases requiring a large volume of contrast. Management of AKI is as per the general intensive care population. Timing of commencement of renal replacement therapy should factor in the impact of hypervolaemia secondary to cardiopulmonary bypass and transfusion in the inflamed patient, and intervention may be required earlier for fluid removal to prevent respiratory decompensation. Consideration should also be given in patients with residual dissection in the descending aorta as further imaging may be required to exclude malperfusion.

Recurrent Laryngeal Nerve Injury

The vagus nerve, after leaving the medulla, passes on the left with the common carotid artery and then anterior to the aorta in the mediastinum. The left recurrent laryngeal nerve branches from the vagus and passes medially under the aorta and then continues inferiorly in the tracheo-oesophageal groove.[55],[56] Iatrogenic damage during surgery is most frequently associated with left-sided injury[57] and can lead to unilateral vocal fold paralysis.

Signs indicative of injury include new hoarse or breathy voice, dysphagia, weak cough or suggestion of repeated aspiration due to the inability of the contralateral fold to complete glottic closure.[58] Studies suggest up to 26% of patients undergoing surgery to the aortic arch or descending aorta suffer post-operative unilateral vocal fold paralysis.[57] Respiratory complications are common due to poor secretion clearance and aspiration pneumonia. Requirement for reintubation, bronchoscopy and tracheostomy is higher and patients with vocal fold paralysis have both a longer critical care and hospital stay and a higher overall mortality. [59,60]

Silent aspiration is common and so assessment of swallowing using videofluoroscopic swallow study (VFSS) or fibreoptic endoscopic evaluation of swallowing (FEES) should be considered as standard approaches may be unreliable. Where unilateral vocal fold paralysis is identified, patients should be referred to an ear, nose and throat (ENT) specialist for assessment and ongoing management.

Post-ICU Management

Following the acute post-operative period and when blood pressure targets can be relaxed, controlling hypertension is associated with reduced aorta-related adverse events. Agents used in this period may include beta-blockers, ACE inhibitors and angiotensin receptor blockers. [31] Lipid profile optimisation and smoking cessation as steps to reduce atherosclerosis formation are also recommended, although evidence is limited. [20]

A long-term programme of monitoring to detect complications and avoid emergencies in treated and untreated sections of the aorta is required. [20] Patients undergoing TEVAR continue to require follow-up as there are higher rates of re-intervention compared to patients undergoing open surgery, with 39.1% of patients requiring further intervention in the following 10-year period. Re-intervention is usually due to the presence of an endoleak, perfusion of the false lumen, aortic dilatation and retrograde dissection, although in the majority of cases, this can also be completed endovascularly. [61]

In patients with aortic disease, particularly those presenting at a young age, it is essential to take a comprehensive family history to consider the presence of an underlying genetic disorder. [41] Some may have characteristic features of a connective tissue disease so screening the patient and their first-degree relatives is important. Where patients are recognised to be at risk of aortic disease due to a genetic mutation, close monitoring with a programme of lifestyle modification including blood pressure control, regular imaging and early intervention will limit morbidity and mortality.

Management of Aortic Dissection in Pregnancy

In patients with diagnosed aortopathy, pregnancy is associated with an increased risk of aortic dissection. Marfan's syndrome, Loeys-Dietz syndrome, Turner's syndrome and vascular Ehlers-Danlos are all heritable conditions and so genetic counselling prior to pregnancy is recommended, along with a discussion of the risks of dissection. Where pregnancy is planned, imaging of baseline aortic dimensions should be performed. Blood pressure should be controlled in line with local guidelines to ensure avoidance of hypertension and beta-blockade is recommended unless contraindicated. Surveillance TTE should be performed as a minimum in each trimester and into the post-partum period to ensure no measurable growth of the aorta. [27] A management plan involving an MDT, including a foetal medicine specialist and cardiologist is essential, and ideally, delivery should be planned at hospital with on-site aortic surgery services.

The risk of type A dissection is related to the degree of dilatation of the aortic root (aortic diameter: low risk <4.0 cm, high risk >4.5 cm) and this will inform the decision making between the clinical team and the patient regarding the mode of delivery. Type B dissection may occur without significant dilatation of the aorta and accounts for 20%–40% of dissections in patients with Marfan's syndrome. Aortic dissection may occur at any stage of pregnancy, but particularly during the period from the third trimester to 12 weeks post-partum. [62] Type A dissection is described more frequently in the third trimester, with type B dissection more frequently in the post-partum period. [63] Clinical teams throughout this period must therefore be aware of the signs and symptoms of aortic dissection, even after delivery.

Management of type A dissection in the pregnant patient is complex and influenced by the risk of maternal mortality, the risk of foetal loss if the pregnancy continues and the risk of neonatal prematurity if a caesarean section is performed. [64] Clinical practice is predominantly based on the outcomes of case series versus formal guidelines, due to the paucity of evidence. Type A dissection prior to 24 weeks gestation would usually be treated primarily with emergency aortic surgery as described. Where possible, one case series described consideration of a period of conservative management until the second trimester for those presenting in early pregnancy, to allow foetal organogenesis.[65] Surgery was then undertaken with foetal monitoring during the peri-operative period whilst recognising the high risk of foetal loss. After 24 weeks where there is potential for foetal survival emergency caesarean section is usually advocated, followed by aortic surgery. Type B dissection should be managed medically in the absence of signs of malperfusion. Where malperfusion is present, an endovascular management strategy is still preferred.[64, 66]

Overview of respiratory failure in ICU

Shailesh Bihari and Andrew Bersten

Respiratory failure is common in intensive care unit (ICU).[1–3] It can be classified as acute, acute-on-chronic or chronic. The clinical presentation of acute respiratory failure (ARF) is typically dramatic, and may have profound derangements in blood gas values; however, with careful observation, ARF can often be recognised prior to this. Chronic respiratory dysfunction may present with markers of chronic hypoxaemia (e.g. polycythaemia or *cor pulmonale*) and may or may not require ICU care. Acute-on-chronic respiratory failure represents an acute deterioration in the presence of pre-existing chronic pulmonary disease which demands modifications to specific management. Regardless of acuity, respiratory failure represents a potentially life-threatening group requiring urgent management to prevent and treat rapid clinical deterioration.

ARF is characterised by the rapid onset of severe impairment of pulmonary gas exchange and the inability of the lungs to meet the body's metabolic needs for the transport of oxygen (O_2) into the blood and/or the removal of carbon dioxide (CO_2) from the blood. Although the diagnosis of ARF is typically based on the measurements of arterial blood gas (ABG) parameters (i.e. partial pressure of oxygen [PaO_2], partial pressure of carbon dioxide [$PaCO_2$], bicarbonate and pH), these values must be interpreted in relation to the patient's baseline status (Table 36.1); however, careful observation at the bedside is equally important and includes increased respiratory effort and overall distress.

Table 36.1

Changes in arterial blood gas in acute and chronic respiratory failure

$PaCO_2$ (normal 40 mm Hg)	pH change (normal 7.4)	Bicarbonate change (range 22–24 mmol/L)
Respiratory acidosis ↑10 mm Hg	Acute↓0.08	Acute↑1 mmol/L
	Chronic↓0.03	Chronic↑3 mmol/L
Respiratory alkalosis ↓10 mm Hg	Acute↑0.08	Acute↓2 mmol/L
	Chronic↑0.03	Chronic↓5 mmol/L

Increased respiratory effort is manifested by increased work of breathing (WOB) related to elastic work (high negative pleural pressure with the use of accessory muscles), resistive work (forced expiration) and increased respiratory rate. As respiratory rate is the most poorly recognised vital sign, this emphasises the need for careful observation. If increased respiratory rate reflects compensation for metabolic acidosis it will not be accompanied by other features of high WOB and does not constitute respiratory failure per se.

Respiratory System Components

Respiratory control is established by the tight coordination of three groups of neurons in the medulla oblongata: a dorsal respiratory centre that controls inspiration, a ventral respiratory group that controls expiration and a pneumotaxic centre that controls the rate and depth of breathing. [4] In addition to neurons in the brainstem, a peripheral chemoreceptor system is located outside the brain in the form of the carotid aortic bodies that detect subtle changes in PaO_2 . The neural impulses from the central nervous system traverse the spinal cord and motor neurons, reaching and activating the diaphragm and other respiratory muscles. Contraction of the inspiratory muscles creates negative pleural pressure by expanding the chest cavity and pushing the abdominal contents caudally. The negative pressure created in the thorax during inspiration leads to sub-atmospheric pressure in the alveoli, creating a gradient for the flow of inspired air toward the alveoli.

The respiratory control centre responds to altered levels of CO_2 and O_2 by changing the respiratory rate and pattern. This forms the basis of apnoea testing in brain-dead patients where the total absence of respiratory effort is seen with an increase in CO_2 levels (intense ventilatory stimulus, i.e. respiratory acidosis).[5] However, in patients with chronic hypercapnia such as those with COPD, respiratory drive is predominantly hypoxia-driven and these patients should be given titrated oxygen therapy with a target of 88%–92% oxygen saturation to reduce both hypoxia and the risk of hypercapnia (from reduced respiratory drive with excess oxygen).[6]

Environmental oxygen uptake via the lungs acts as a substrate for energy production. Aerobic respiration is the most efficient mechanism for adenosine triphosphate (ATP) production by oxidative phosphorylation, which serves as the fuel to maintain cellular homeostasis and metabolism. Absence or lack of ATP leads to loss of cellular integrity initially, followed by cellular and later organism death. Under hypoxic conditions, ATP production becomes less efficient (through glycolysis) and leads to the production of lactic acid. An understanding of the common pathways and significance of cellular hypoxia is vital to providing appropriate and safe support and treatment to the acutely unwell patient.

Oxygen Delivery

Transport of oxygen to the cells can be divided into six simple steps reliant only on the laws of physics: (1) convection of oxygen from the environment into the body via the lungs (ventilation); (2) diffusion of oxygen into the blood through the alveolar–capillary membrane (oxygen uptake); (3) reversible chemical bonding with haemoglobin; (4) convective transport of oxygen to the tissues (cardiac output [CO]); (5) diffusion into the cells and organelles; and (6) the redox state of the cell (i.e. the cell is largely autonomous and uses what it needs).[7] Although adequate oxygen delivery is important, excess oxygen is at least theoretically of no benefit

Under normal circumstances and during resting conditions, the systemic oxygen delivery (DO_2) (total amount of oxygen delivered to the tissues per minute), is more than adequate to meet the body's oxygen consumption (VO_2) and this ensures that aerobic metabolism is maintained. The oxygen extraction ratio is usually around 25% under healthy conditions, and can compensate for moderate changes; however, when perturbations are severe, either a major decrease in oxygen delivery (low cardiac output, anaemia, low FIO_2, ventilation–perfusion mismatch, right to left shunt, lung diffusion abnormalities etc.) or a major increase in oxygen demand (such as exercise, inflammation, fever, agitation, seizures, hypermetabolic states) there is a risk of mismatch and the reliance on anaerobic metabolism. The level of $\dot{D}_{O_2}$ at which $\dot{D}_{O_2}$ begins to decline has been termed 'critical $\dot{D}_{O_2}$' and is approximately 300 mL/min in an adult.[8] 'Shock' is the usual term used in this situation, defined broadly as failure of oxygen delivery to match tissue demand.

Failure of oxygen delivery to the cells leads rapidly to cellular dysfunction and can lead to cellular death and organ dysfunction culminating in the organism's death. $\dot{D}_{O_2}$ drives the $\dot{D}_{O_2}$ requirement, and failure of $\dot{D}_{O_2}$ to match $\dot{V}_{O_2}$ results in reduction in aerobic metabolism and energy production, necessitating ATP production by the less-efficient glycolytic pathway.

Carbon Dioxide Removal

Carbon dioxide is transported in the blood from body tissues to the lungs by one of three methods: dissolution directly into the blood, binding to haemoglobin or carried as the bicarbonate ion.[9] Several properties of CO_2 in the blood affect its transport. First, carbon dioxide is more soluble in blood than oxygen. About 5% to 7% of all carbon dioxide is dissolved in the plasma. Second, CO_2 can bind to plasma proteins or can enter red blood cells and bind to haemoglobin. This form transports about 10% of the CO_2. When carbon dioxide binds to haemoglobin, a molecule called carbamino-haemoglobin is formed. The increased capacity of blood to carry CO_2

under conditions of decreased haemoglobin saturation (Haldane effect) facilitates the removal of CO_2 from the tissues.[10] Binding of CO_2 to haemoglobin is reversible. Therefore when it reaches the lungs, the CO_2 can freely dissociate from the haemoglobin and be expelled from the body. Third, the majority of CO_2 molecules (around 85%) are carried as part of the bicarbonate buffer system. As CO_2 is lipid-soluble, it crosses the blood-brain barrier rapidly; thus changes in $PaCO_2$ are sensed rapidly in the brain, producing changes in pH and ventilation. However critical illness affects the patient's respiratory drive through multiple mechanisms, mainly operating through three feedback systems: cortical, metabolic and chemical. The main determinant of respiratory drive in many critically ill patients is chemical feedback, which is the response of the respiratory centre to changes in ABGs and pH. Systemic inflammation and afferents from the lung and chest wall may also have a strong influence on the respiratory centre, and can increase respiratory drive for a given chemical stimulus.

Pathophysiologic Processes Leading to ARF

ARF can be a consequence of a wide range of defects, which can have both pulmonary and extra-pulmonary aetiologies. It is important to understand the mechanisms leading to hypoxaemia and hypercapnia, as the best therapeutic approach may require targeting the appropriate aetiology. This, however, is often difficult in the early stages of managing a patient with ARF. Considering a broad differential diagnosis for ARF is crucial to the appropriate management of the underlying condition.

Pulmonary Gas Exchange

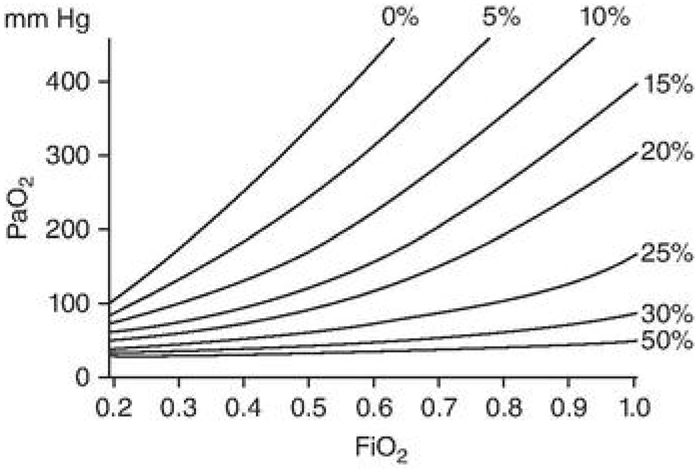
The efficiency of gas exchange in the lungs is determined by the balance between alveolar ventilation and pulmonary capillary blood flow.[11, 12] This balance is commonly expressed as the ventilation–perfusion (V/Q) ratio. The influence of V/Q ratios on pulmonary gas exchange can be described using an alveolar–capillary unit, and a perfect match between ventilation and perfusion ($V/Q = 1$). This is the reference point for defining the abnormal patterns of gas exchange. In a healthy individual, the V/Q ratio is 1 at the middle of the lung, with a minimal spread of V/Q ratios from 0.3 to 2.1 from base to apex.

Shunt

A V/Q ratio below 1.0 occurs when pulmonary capillary blood flow is excessive relative to ventilation. The excess blood flow, known as *intrapulmonary shunt* , does not participate in pulmonary gas exchange. There are two types of intrapulmonary shunt.

True shunt , which indicates the total absence of gas exchange between capillary blood and alveolar gas ($V/Q=0$), and *anatomic shunt* between the right and left sides of the heart; they are functionally equivalent.

The shunt fraction also determines the influence of inhaled oxygen on the arterial PO_2 (Fig. 36.1). As intrapulmonary shunt increases from 10% to 50%, an increase in fractional concentration of inspired oxygen (FiO_2) produces less of an increment in the arterial PO_2 . When the shunt fraction exceeds 50%, the arterial PO_2 is independent of changes in FiO_2 , and the condition behaves like a true (anatomic) shunt. This means that, in conditions associated with a high shunt fraction (e.g. acute respiratory distress syndrome), the FiO_2 can often be lowered to non-toxic levels (FiO_2 below 60%) without further compromising arterial oxygenation.



The graph features two axes. The vertical axis reads partial pressure of arterial oxygen in millimetres of mercury and extends from zero to four hundred. The horizontal axis reads fraction of inspired oxygen and extends from zero point two to one point zero. Several curves plot the relationship between these two variables. Each curve corresponds to a percentage label, which reads from top to bottom as zero percent, five percent, ten percent, fifteen percent, twenty percent, twenty five percent, thirty percent, and fifty percent. The curves start near the bottom left and rise gradually toward the top right.

FIG. 36.1 The iso-shunt diagram, illustrating the relationship between PaO_2 and FiO_2 in the presence of a shunt corresponding to different percentages of total lung blood flow.

Venous admixture represents the capillary flow that does not equilibrate completely with alveolar gas ($0 < V/Q < 1$). As the venous admixture increases, the V/Q ratio decreases until it becomes a true shunt ($V/Q=0$). The fraction of the cardiac output that represents intrapulmonary shunt is known as the *shunt fraction* . In normal subjects, intrapulmonary shunt flow (Qs) represents less than 10% of the total cardiac output (Qt), so the shunt fraction (Qs/Qt) is less than 10%.[11–13] Intrapulmonary shunt fraction is increased in situations such as small airway occlusion such as asthma or when the alveoli are filled with fluid; for example, pulmonary oedema, pneumonia or when the alveoli collapse; for example atelectasis or when the capillary flow is excessive; for example, in non-embolised regions of the lung in pulmonary embolism. The PaO_2 falls progressively as the shunt fraction increases, but the $PaCO_2$ remains constant until the shunt fraction exceeds 50%.[13] The $PaCO_2$ is often below normal in patients with increased intrapulmonary shunt as a result of hyperventilation triggered by the disease process or by the accompanying hypoxaemia. The hypoxaemia in acute respiratory distress syndrome (ARDS) patients is caused by the presence of shunt or units of very low ratio of ventilation to perfusion.[14] Patent foramen ovale (PFO) causing right to left shunt was initially thought to be common in ARDS, is less frequent and never large or extensive and not related to outcome.[15]

Diffusion limitation occurs when the oxygen transport across the alveolocapillary membrane is impaired. Diffusion limitation may be due to a decrease in lung surface area for diffusion, inflammation, and fibrosis of the alveolocapillary membrane, low alveolar oxygen and extremely short capillary transit time. Since CO_2 is 20 times more soluble in water than O_2,[16] it is less likely to be affected by diffusion limitation. Important causes of diffusion limitation are emphysema and interstitial lung disease.[17]

Dead Space Ventilation

A V/Q ratio above 1.0 describes the condition where ventilation is excessive relative to pulmonary capillary blood flow. Excess ventilation, known as *dead space ventilation,* does not participate in gas exchange with the blood. Dead space ventilation includes *anatomic dead space*, which is the gas in the large conducting airways that do not come in contact with capillary blood (about half of the anatomic dead space is in the pharynx), and *alveolar dead space*, which is alveolar gas that does not equilibrate fully with capillary blood. The sum of anatomic and alveolar dead space is termed physiologic dead space. In normal subjects, dead space ventilation (V_d) accounts for 20% to 30% of the total ventilation (V).[11, 12] The

Enghoff modification of the Bohr equation uses arterial CO_2 instead of alveolar CO_2 is commonly used to calculate the physiologic dead space. [18]

$$V_d/V_t = PaCO_2 - P_ECO_2/PaCO_2.\ P_ECO_2 \text{ is the mixed expired partial pressure of } CO_2$$

Dead space ventilation increases in the following situations such as when the alveolar–capillary interface is destroyed; for example emphysema or when blood flow is reduced; that is, low cardiac output or when alveoli are over-distended; for example during positive-pressure ventilation. Hypercapnia usually appears when the V_d/V_t is above 50%. [19]

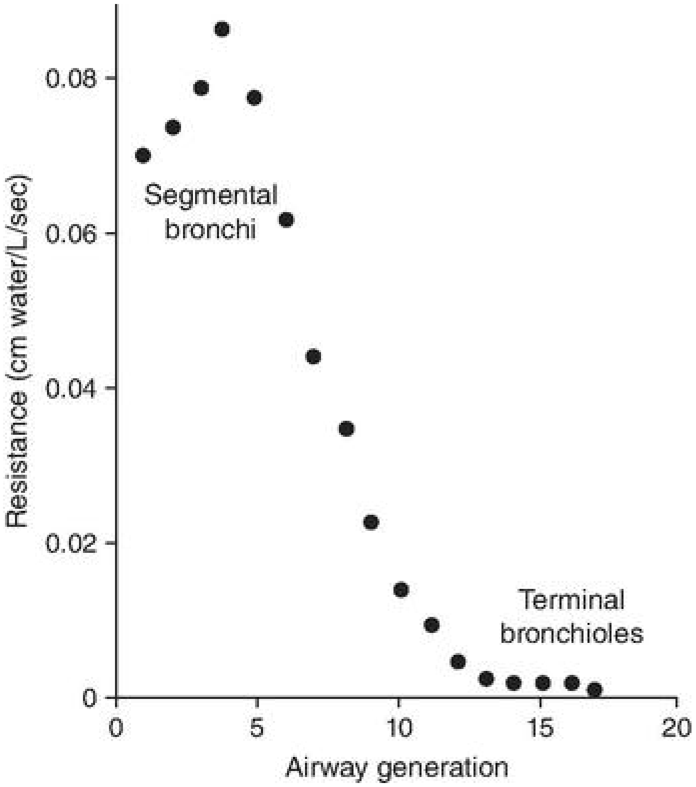
Respiratory Mechanics Considerations

Respiratory mechanics refer to the expression of lung function through measures of pressure and flow. From these, a variety of derived indices can be determined, such as flow, pressure, volume, compliance, resistance and WOB. [20]

Airway Resistance

Respiratory system resistance is mainly a combination of resistance to gas flow in the airways and resistance to deformation of tissues of both the lung and chest wall. The airway resistance in normal airways where the flow is mainly laminar (turbulent flow is localised to the upper airways) increases in proportion to flow rate and is described by the Hagen-Poiseuille equation, being affected by the airway length, fourth power of airway diameter and gas viscosity. Airway resistance in turbulent flow increases exponentially with flow rate, and the main determinant of the rate of pressure change is the density of the gas which provides the rationale for the use of heliox in patients with asthma or upper airway obstruction (by reducing density heliox converts turbulent flow into more efficient laminar flow). [21]

Airway radius has a powerful effect on airway resistance so one might expect that the early and larger generations of airways would offer the least resistance to flow, and resistance would increase as we descended deeper into the lung to the smaller and later airway generations. However, the highest point of resistance is actually the midsize bronchioles (Fig. 36.2) as the lower and smaller airways are much more numerous, and so collectively they have a greater cross-sectional area and therefore offer less resistance. When the radius is reduced by disease, such as during inflammation of the airway wall or contraction of airway smooth muscle causing bronchoconstriction, resistance is markedly increased and to maintain flow, the pressure differential must be increased. Increasing this pressure differential means increasing the WOB and may contribute to respiratory failure.



The scatter plot features two axes. The vertical axis shows resistance in centimetres of water per litre per second and extends from zero to zero point zero eight. The horizontal axis shows airway generation and extends from zero to twenty. A cluster of points near the top left, around airway generation five, reaches higher on the vertical axis and bears the label segmental bronchi. Another cluster of points near the right, around airway generation fifteen to twenty, sits lower on the vertical axis and bears the label terminal bronchioles. Each point represents a measurement of resistance at a specific airway generation.

FIG. 36.2 Airway resistance in the bronchial tree.

Finally, as the lung volume increases, airway resistance falls exponentially. The inverse is also true, that as lung volume decreases, and airway radius declines, there is a rise in airway resistance.

Compliance [22]

Respiratory system compliance is a measure of the elasticity, or distensibility, of the lung and chest wall, and is expressed through the relationship of pressure and volume. [23] Lung compliance reflects both the aerated lung size and the intrinsic stiffness of the lung tissue. During mechanical ventilation (MV) in the ICU or operating room, excessive airway pressure, a plateau pressure >30 cmH $_2$ O, suggests lung damage may be occurring. The most basic estimates of respiratory system compliance use static or dynamic methods.

Static compliance: This represents respiratory system compliance at a given fixed volume when there is no airflow, and the muscles are relaxed. In the conscious individual, it is difficult to achieve respiratory muscle relaxation. In a paralysed individual, as in the operating theatre, it is straightforward to measure static compliance.

$$\text{Cstat} = \text{V}/(\text{Pplat} - \text{PEEP}),\ \text{where Pplat is plateau pressure, PEEP is positive end expiratory pressure, and V is volume.}$$

Dynamic compliance: This uses the continuous measurement of pressure and volume during relaxed breathing. See Chapter 38 for more detailed methods.

Work of Breathing (WOB)

WOB is the amount of energy or O $_2$ consumption needed by the respiratory muscles to produce enough ventilation and respiration to meet the metabolic demands of the body. WOB = the cumulative product of pressure X volume of air moved each instant. This is required to overcome, the elastic work at ~65% and non-elastic (resistance) work at ~35% (80% airflow resistance and 20% viscoelastic resistance)

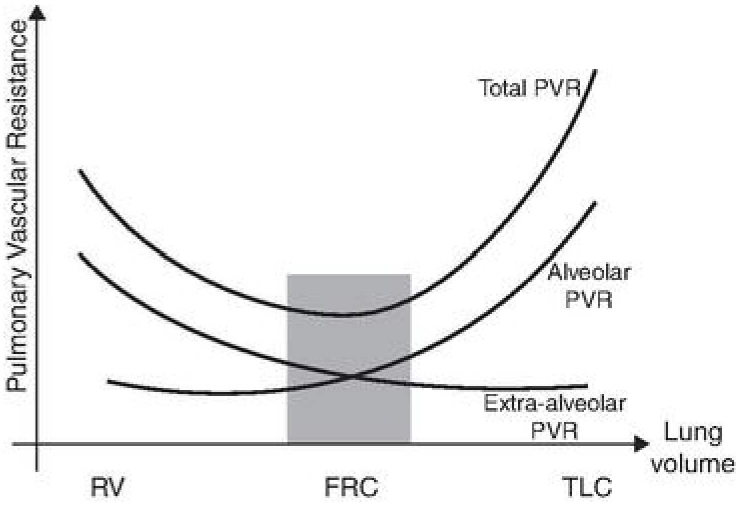
Clinical significance

In mechanically ventilated, healthy subjects the respiratory system static compliance is 50–100 mL/cmH_2O, and airway resistance (including endotracheal tube) = 4–8 cmH_2O/L/s. Patients with ARDS or cardiogenic pulmonary oedema have low compliance and elevated resistance due to reduced lung volume. Patients with COPD or asthma typically have high compliance and higher resistance.

Under normal resting circumstances, the oxygen consumption (V_{O2}) attributed to WOB is about 1%–2% of V_{O2}. In individuals with respiratory failure, both WOB and attributable oxygen consumption can rise dramatically.

Pulmonary vascular resistance

A U-shaped association between lung volume and pulmonary vascular resistance exists. As lung volumes approach total lung capacity (TLC), blood vessels within the alveoli (intra-alveolar vessels) become compressed leading to increases in resistance. As lung volumes drop below functional residual capacity, distal airways collapse causing alveolar hypoxia and hypoxic pulmonary vasoconstriction. In contrast, blood vessels within the lung parenchyma (extra-alveolar vessels) actually dilate during inspiration due to an increase in radial interstitial forces. Both intra-alveolar and extra-alveolar vessels serve as channels for pulmonary flow, so their net effect on PVR is represented by the solid curve in Fig. 36.3 . At FRC, PVR is at its nadir.



The graph features two axes. The vertical axis reads pulmonary vascular resistance and extends upward. The horizontal axis reads lung volume and extends from left to right with labels residual volume, functional residual capacity, and total lung capacity in sequence. Three curves appear on the graph. The curves are labelled total pulmonary vascular resistance, alveolar pulmonary vascular resistance and extra alveolar pulmonary vascular resistance. A shaded rectangular area highlights the functional residual capacity region where the curves intersect.

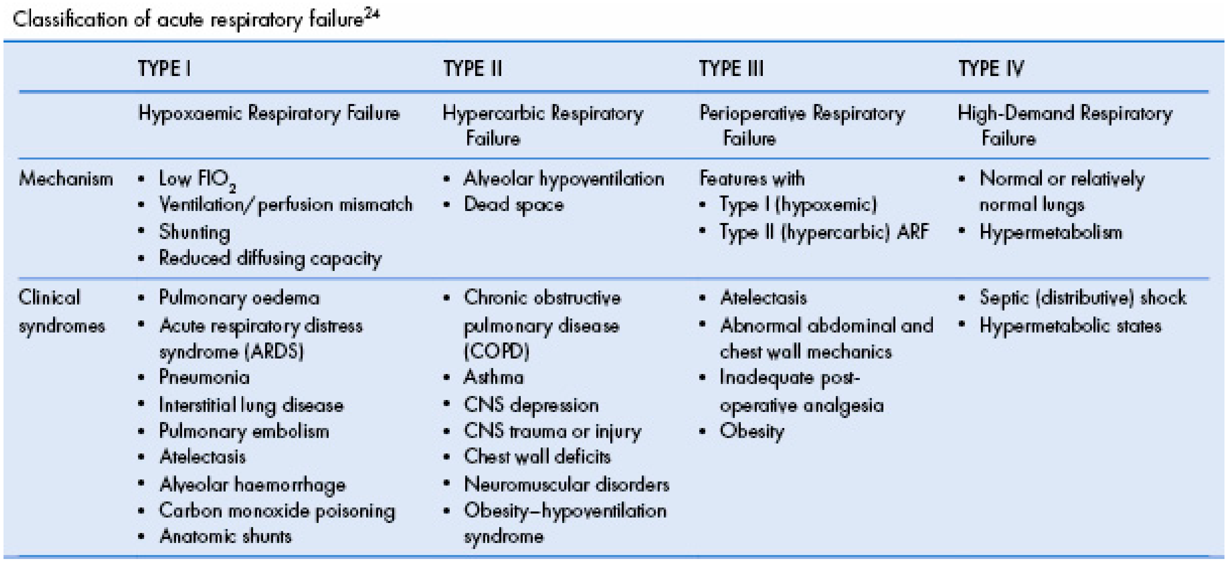
FIG. 36.3 Relationship between pulmonary vascular resistance and lung volumes. *FRC* , Functional residual capacity; *PVR* , pulmonary vascular resistance; *RV* , residual volume; *TLC* , total lung capacity.

The clinical importance of this is seen in a patient with pulmonary hypertension on MV. Besides the typical treatments (oxygen, avoiding hypercarbia/acidosis, right ventricular afterload reducing therapy), it is imperative that tidal volume and FRC are considered to avoid increases in PVR and right ventricular afterload potentially precipitating acute right heart failure.

Classification of Arf

ARF has been classically described as either hypoxaemic or hypercarbic failure; however, Table 36.2 describes differences among four types of ARF with regard to the mechanism and clinical syndromes. [24] Despite these categories, considerable overlap exists in the different types of ARF, and a given patient can have multiple types of ARF contributing to their clinical presentation.

Table 36.2



Classification of acute respiratory failure[24]

	TYPE I	TYPE II	TYPE III	TYPE IV
	Hypoxaemic Respiratory Failure	Hypercarbic Respiratory Failure	Perioperative Respiratory Failure	High-Demand Respiratory Failure
Mechanism	• Low FIO_2 • Ventilation/perfusion mismatch • Shunting • Reduced diffusing capacity	• Alveolar hypoventilation • Dead space	Features with • Type I (hypoxemic) • Type II (hypercarbic) ARF	• Normal or relatively normal lungs • Hypermetabolism
Clinical syndromes	• Pulmonary oedema • Acute respiratory distress syndrome (ARDS) • Pneumonia • Interstitial lung disease • Pulmonary embolism • Atelectasis • Alveolar haemorrhage • Carbon monoxide poisoning • Anatomic shunts	• Chronic obstructive pulmonary disease (COPD) • Asthma • CNS depression • CNS trauma or injury • Chest wall deficits • Neuromuscular disorders • Obesity–hypoventilation syndrome	• Atelectasis • Abnormal abdominal and chest wall mechanics • Inadequate post-operative analgesia • Obesity	• Septic (distributive) shock • Hypermetabolic states

Type I or ‘Hypoxaemic’ Respiratory Failure

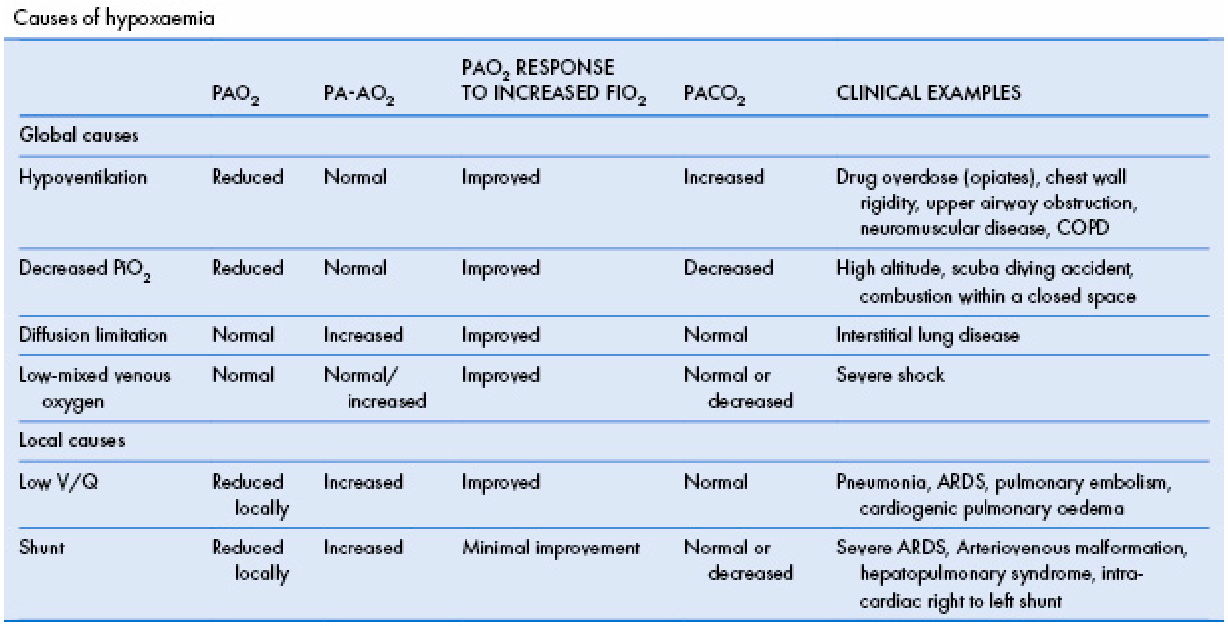
Type I ARF is the most common form of respiratory failure, and at sea level is defined as a $PaO_2 < 60$ mm Hg, with normal or decreased $PaCO_2$. [24] In ICU patients PaO_2/FiO_2 is used to classify their severity. [25]

The terms hypoxia and hypoxemia are not synonymous. Hypoxemia is defined as a decrease in the partial pressure of oxygen in the blood whereas hypoxia is defined as a reduced level of tissue oxygenation. It can be due to either defective delivery or defective utilisation of oxygen by the tissues. There are many causes of hypoxia and hypoxaemia (Tables 36.3 and 36.4).

Decreased PaO_2 can be caused by hypoventilation, lower PO_2 in inspired air, diffusion limitation, low V/Q regions or shunt. In contrast with other causes, hypoxaemia due to shunt characteristically responds poorly to increased FiO_2 (Fig. 36.3). [26, 27] Low V/Q regions and shunt are by far the most common causes of clinically encountered hypoxaemia.

Table 36.3

Table 36.4



Causes of hypoxaemia

	PAO_2	$PA\text{-}AO_2$	PAO_2 RESPONSE TO INCREASED FIO_2	$PACO_2$	CLINICAL EXAMPLES
Global causes					
Hypoventilation	Reduced	Normal	Improved	Increased	Drug overdose (opiates), chest wall rigidity, upper airway obstruction, neuromuscular disease, COPD
Decreased PiO_2	Reduced	Normal	Improved	Decreased	High altitude, scuba diving accident, combustion within a closed space
Diffusion limitation	Normal	Increased	Improved	Normal	Interstitial lung disease
Low-mixed venous oxygen	Normal	Normal/ increased	Improved	Normal or decreased	Severe shock
Local causes					
Low V/Q	Reduced locally	Increased	Improved	Normal	Pneumonia, ARDS, pulmonary embolism, cardiogenic pulmonary oedema
Shunt	Reduced locally	Increased	Minimal improvement	Normal or decreased	Severe ARDS, Arteriovenous malformation, hepatopulmonary syndrome, intra-cardiac right to left shunt

---

FiO_2, Inspired O_2 fraction; *$PA\text{-}aO_2$*, alveolar-arterial O_2 difference; *PAO_2*, alveolar pressure of oxygen; *PaO_2*, arterial pressure of oxygen; *PiO_2*, partial pressure of O_2 in inspired gas; *V/Q*, ventilation to perfusion ratio.

Hypoxaemia is almost always the result of respiratory failure, but it can also be the result of cardiac abnormalities. A low cardiac output can aggravate hypoxaemia via a reduction in oxygen saturation of the mixed venous blood (SvO_2) leading to a failure to fully arterialise pulmonary venous blood. Moderate hypoxaemia must be compensated for by an increase in cardiac output, which may be poorly tolerated in frail patients.

Hypoxaemia can be compensated for by an increase in cardiac output, so that DO_2 may not be critically reduced by its presence. The increase in cardiac output that accompanies hypoxemia is mediated by an increase in sympathetic tone, resulting in combined increases in heart rate and contractility. Impaired O_2 delivery to the tissues is more often the result of decreased cardiac output or altered vascular tone than of a decrease in PaO_2. Tissue hypoxia is a hallmark of shock and is associated with altered cellular metabolism, including decreased lactate clearance, which results in increased blood lactate levels.

Decreased alveolar oxygen content, though affected by the partial pressure of O_2 in inspired gas, is also affected by $PaCO_2$, which typically results from hypoventilation (e.g. central respiratory depression and neuromuscular weakness). Hence, unless there is an increase in the concentration of inspired oxygen, PAO_2 can decrease in the presence of an increased $PaCO_2$. $PaCO_2$ can rise with an increase in CO_2 production (increased metabolism), a decrease in minute ventilation (e.g. because of central respiratory depression or neuromuscular weakness) and/or an increase in dead space ventilation.

The nonlinear relationship between SaO_2 and PaO_2 is affected by body temperature, partial pressure of carbon dioxide in arterial blood ($PaCO_2$) pH, and 2,3-diphosphoglycerate concentration (Table 36.5). As a result, patients can have a higher or lower SaO_2 for a given PaO_2, depending on the existing conditions. The critical PaO_2 value is approximately 60 mm Hg because a further decline in PaO_2 results in a steep fall in SaO_2.

Table 36.5

Factors influencing the position of the oxygen dissociation curve

FACTORS INCREASING P50 (CURVE SHIFTS TO THE RIGHT)	FACTORS DECREASING P50 (CURVE SHIFTS TO THE LEFT)
Hyperthermia	Hypothermia
Decreased pH (acidaemia)	Increased pH (alkalaemia)
Increased Pco_2 (Bohr effect)	Decreased Pco_2
Increased 2,3 DPG	Decreased 2,3 DPG Foetal haemoglobin Carbon monoxide Methaemoglobin

DPG , Diphosphoglycerate; *P50* , the partial pressure of oxygen when haemoglobin is 50% saturated with oxygen.

Common causes of type 1 respiratory failure in ICU are those caused by hypoventilation, low VQ ratio and shunt (Table 36.4).

Type II or ‘Hypercarbic’ Respiratory Failure

Type II ARF ($PaCO_2$ >45 mm Hg/6.0 kPa) represents the failure of the lungs to remove a sufficient amount of CO_2 in a given time interval and is characterised by decreased alveolar minute ventilation. An increase in $PaCO_2$ leads to hypoxemia because CO_2 displaces O_2 and effectively reduces the alveolar partial pressure of oxygen (PAO_2). In contrast to some cases of type I ARF, hypoxaemia in type II ARF is rather easily corrected with supplemental oxygen. This type of respiratory failure is frequently the result of acute or chronic neuromuscular dysfunction or the inability of the airways or lungs to ensure adequate ventilation and CO_2 exchange[9] (Table 36.6).

Table 36.6

Causes of alveolar hypoventilation [9]

ACUTE ONSET	INSIDIOUS ONSET
Decreased central drive Drugs (sedatives) Central nervous system diseases (encephalitis, stroke, trauma)	*Lung and airways diseases* Chronic obstructive airway disease (bronchitis, emphysema, bronchiectasis)
Altered *neural and neuromuscular* transmission Spinal cord trauma Transverse myelitis Tetanus Amyotrophic lateral sclerosis Poliomyelitis Guillain-Barré syndrome Myasthenia Gravis Organophosphate poisoning Botulism	*Chest wall abnormalities* Kyphoscoliosis Thoracoplasty Obesity Pleural effusion Neuromuscular disorders
	Lung and chest wall diseases Scleroderma Polymyositis Systemic lupus
Muscle abnormalities Muscular dystrophy Disuse atrophy	Central nervous system abnormalities Primary alveolar hypoventilation
	Other Electrolyte abnormalities Malnutrition Endocrine disorders
Chest wall and pleural abnormalities Acute hyperinflation Chest wall trauma (flail chest, diaphragmatic rupture)	

ACUTE ONSET	**INSIDIOUS ONSET**
Lung and airways diseases Acute asthma Acute exacerbation of chronic obstructive pulmonary disease Cardiogenic and noncardiogenic pulmonary oedema Pneumonia Upper airway obstruction Bronchiectasis	
Other Sepsis Circulatory shock	

Causes

Type 2 respiratory failure is commonly caused by chronic obstructive pulmonary disease (COPD) but may also be caused by chest wall deformities, respiratory muscle weakness and central nervous system (CNS). CNS depression is associated with reduced respiratory drive and is often a side effect of sedatives and strong opioids. It may also be caused by severe asthma, myasthenia gravis, muscle disorders, obesity, hypothyroidism and adult respiratory syndrome.

Mechanistically there are three major causes of this type of failure leading to hypercapnia.[28], [29] (1) The output of the respiratory centres controlling the muscles may be inadequate (anaesthesia, drug overdose and diseases of the medulla), resulting in a central respiratory drive that is insufficient for the demand or the respiratory centres may reflexively modify their output to prevent respiratory muscle injury and avoid or postpone fatigue. (2) There may be a mechanical defect in the chest wall, as is the case in flail chest, diseases of the nerves (Guillain-Barré syndrome) and anterior horn cells (poliomyelitis) or diseases of the respiratory muscles (myopathies). Severe hyperinflation, with flat diaphragm and reduced mechanical action of the inspiratory muscles, as in acute asthmatic attack, is one of the most common causes of impaired mechanical performance of the inspiratory muscles. (3) When working under excessive inspiratory load, the inspiratory muscles may become fatigued, that is, they become unable to continue to generate adequate pleural pressure despite an appropriate central respiratory drive and an intact chest wall.

Type III or ‘Perioperative’ Respiratory Failure

Type III respiratory failure is synonymous with perioperative respiratory failure and is related to atelectasis of the lung. It is often a consequence of abnormal abdominal and chest wall mechanics in the setting of surgery or trauma, especially those characterised by intrapleural or subdiaphragmatic pathologies. The patient usually splints the chest to limit involuntary movement of the injured region, leading to inadequate expansion of the dependent parts of the lungs, with resultant regional atelectasis and hypoventilation. As a result, type III ARF shares features with both type I (hypoxemic) and type II (hypercarbic) ARF. This type of ARF can be prevented or ameliorated by certain anaesthetic strategies in addition to perioperative measures such as elevating the head of the bed, early ambulation, use of continuous positive airway pressure (CPAP), [30] incentive spirometry, avoiding excessive sedation and lowering intraabdominal pressure.

Type IV or ‘High-Demand’ Respiratory Failure

Type IV respiratory failure is related to an inability of normal or relatively normal lungs to keep up with increased ventilatory demands associated with hypermetabolism (e.g. secondary to sepsis). In other words, peripheral tissue demands cannot be satisfied by cardiorespiratory compensatory mechanisms. Under these conditions, respiratory muscle fatigue can lead to a requirement for MV to support adequate minute ventilation.

Diagnostic Workup

Obtaining a relevant history is crucial in narrowing down the aetiology of ARF. A focused physical examination also helps assess the severity of respiratory failure and determine the need for immediate interventions. Common signs include tachypnoea; the use of accessory respiratory muscles; nasal flaring; abdominal paradoxical breathing; and retractions in the intercostal, suprasternal or supraclavicular areas. At times, irregular breathing patterns or poor chest wall excursion may be observed in addition to cough, wheezing, copious secretions or cyanosis. A detailed examination of the upper airway and chest in addition to careful neurologic, cardiovascular, abdominal, skin and musculoskeletal system examinations may also help narrow down the differential diagnosis.

Before the comprehensive diagnostic workup, it is important to remember that establishing a diagnosis should not delay intervention in cases of severe ARF. ABG analysis should be considered in all patients with suspected ARF but is not mandatory. The ABG does help to determine the chronicity of the respiratory failure and, more importantly, the extent and severity of the ARF. The ratio of partial pressure of oxygen in the blood to inspired oxygen concentration also defines the severity of hypoxaemia (normal value of >300 mm Hg or 40 kPa).

Laboratory workup should also include a full blood count, basic biochemical profile, cardiac enzymes and microbiologic evaluation. Chest imaging, including computed tomography (CT) when needed, can help with the diagnosis of a primary pulmonary pathology. Chest radiography is mandatory in any patient with respiratory failure and may reveal abnormalities suggestive of pneumonia, lobar collapse, pulmonary oedema or pneumothorax. Conversely, in asthma or COPD, it might be normal. Transporting critically ill patients is not without risk, but thoracic CT can identify pathologies such as pulmonary emboli, pneumothoraces, small pleural effusions, parenchymal infiltrates and abscess cavities that are not apparent on plain chest radiography. Bronchoscopy with bronchoalveolar lavage and sampling for both cytology and infective causes can be an invaluable aid to diagnosis and to assist management decisions.

Evaluating cardiac function with echocardiography can significantly narrow down the differential diagnosis in patients with systemic disease and shock. Increasing availability and accumulated evidence about the role of point-of-care ultrasound in the ICU has had a significant impact on the management of ARF. [31–33]

Many ICUs use acid–base balance as a simple bedside indicator of global $\dot{D}_{O_2}$. The presence of acidosis and a base deficit of less than −2 may be used to detect evidence of inadequate $\dot{D}_{O_2}$, presuming this reflects lactate accumulation. However, plasma lactate concentration is an unreliable indicator of tissue hypoxia; it represents the balance between production and consumption so, if used in isolation or as a single value to assess $\dot{D}_{O_2}$, can easily mislead.[34] The use of lactate as a marker of $\dot{D}_{O_2}/\dot{V}_{O_2}$ balance is best used as a trend using serial measurements

Management

Prioritising airway patency, breathing and circulation has long been a basic tenet in the management of ARF.[35] Appropriate management of a patient with ARF usually requires admission to an ICU setting, where adequate support and close monitoring are available. Management should focus on stabilisation of the patient's ventilatory and haemodynamic status in addition to correction of the pathophysiologic process underlying the respiratory failure.

Management of Arterial Hypoxaemia

The first action to increase PaO_2 is to increase the FIO_2 . Initially, this is usually achieved via either a variable performance mask or nasal prongs system, or a venturi mask. If the response is unsatisfactory a mask with an oxygen reservoir (i.e. a 'non-rebreather mask') can be used. More recently, the availability of high-flow nasal oxygen systems has revolutionised the care of patients with ARF, but this may only be available in ICU in some hospitals. If the response is still poor, then the patient is likely to have severe V/Q mismatching or a shunt that could require ICU intervention.

Once the above steps have failed consideration of non-invasive ventilation (NIV) may be necessary. The next step should be to try to reopen closed alveoli by repositioning and applying positive-pressure ventilation using CPAP in the absence of endotracheal intubation, or PEEP if the patient is receiving MV (non-invasive or invasive). Relief of an excessive breathing workload and high oxygen consumption often helps restore the balance, allowing effective O_2 delivery. Treatment of specific conditions such as acute pulmonary oedema, pneumonia, ARDS, asthma and COPD are covered elsewhere.

Ventilatory/Oxygenation Support Strategies and Mechanical Ventilation

The purpose of MV is to improve ventilatory gas exchange in terms of oxygen and carbon dioxide transport. This will hopefully correct hypoxaemia and hypercarbia. See Chapter 42 .

Acute respiratory distress syndrome

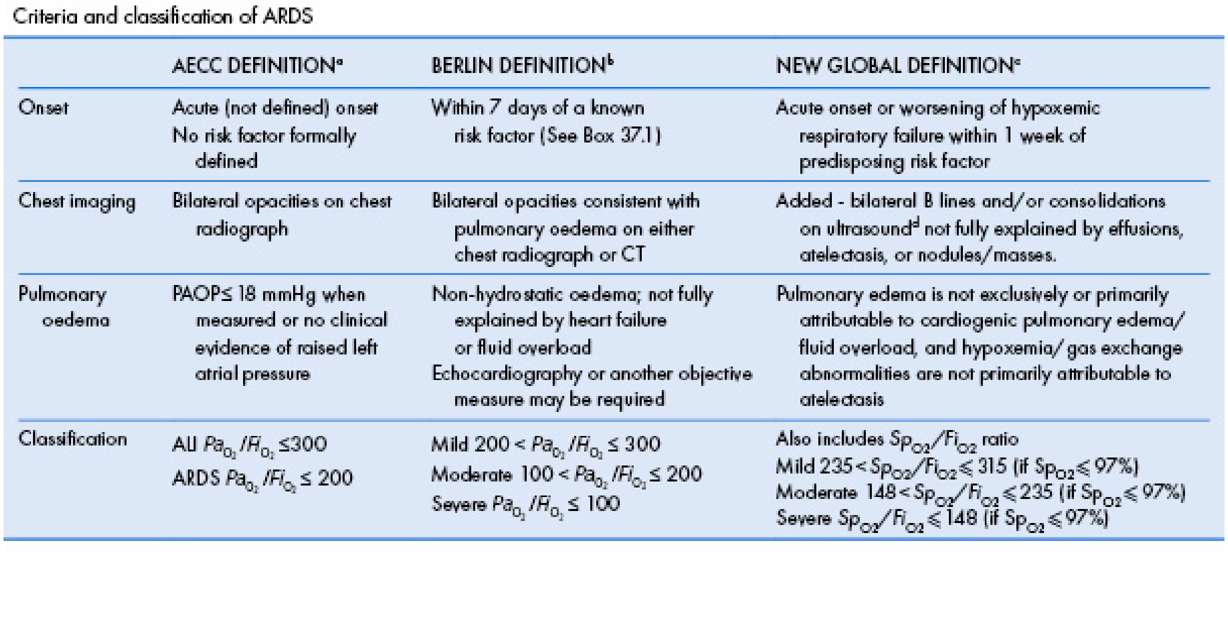
Andrew Bersten and Shailesh Bihari

The acute respiratory distress syndrome (ARDS) was first described in 1967 by Ashbaugh and colleagues as the ‘acute onset of tachypnea, hypoxemia and loss of compliance after a variety of stimuli’. [1] Continued research examining the underlying mechanisms and management strategies is now translating into improved outcome.

Definitions

The ARDS Definition Task Force (the Berlin definition [2]) has replaced the previous American-European consensus definition [3] (Table 37.1). ARDS is classified as mild, moderate and severe based on the Pa_{O_2}/Fi_{O_2} ratio (see Table 37.1). The broad term ‘acute lung injury’ (ALI), which previously referred to cases with a Pa_{O_2}/Fi_{O_2} ratio less than 300 (40 kPa%), has been replaced, and chest radiograph criteria and exclusion of hydrostatic oedema were clarified. Most recently a global definition has been proposed, [4] which includes high flow nasal oxygen as a basis for calculating the severity of hypoxaemia which can be additionally specified using $Sp_{O_2}/FI_{O_2} < 315$ (if $Sp_{O_2} \leq 97\%$), permits ultrasound to be used as an imaging modality for bilateral infiltrates, and, in resource-limited settings does not require PEEP, oxygen flow rate or use of a respiratory support device.

Table 37.1



Criteria and classification of ARDS

	AECC DEFINITION[a]	BERLIN DEFINITION[b]	NEW GLOBAL DEFINITION[c]
Onset	Acute (not defined) onset No risk factor formally defined	Within 7 days of a known risk factor (See Box 37.1)	Acute onset or worsening of hypoxemic respiratory failure within 1 week of predisposing risk factor
Chest imaging	Bilateral opacities on chest radiograph	Bilateral opacities consistent with pulmonary oedema on either chest radiograph or CT	Added - bilateral B lines and/or consolidations on ultrasound[d] not fully explained by effusions, atelectasis, or nodules/masses.
Pulmonary oedema	PAOP≤ 18 mmHg when measured or no clinical evidence of raised left atrial pressure	Non-hydrostatic oedema; not fully explained by heart failure or fluid overload Echocardiography or another objective measure may be required	Pulmonary edema is not exclusively or primarily attributable to cardiogenic pulmonary edema/ fluid overload, and hypoxemia/ gas exchange abnormalities are not primarily attributable to atelectasis
Classification	ALI $Pa_{O_2}/Fi_{O_2} \leq 300$ ARDS $Pa_{O_2}/Fi_{O_2} \leq 200$	Mild $200 < Pa_{O_2}/Fi_{O_2} \leq 300$ Moderate $100 < Pa_{O_2}/Fi_{O_2} \leq 200$ Severe $Pa_{O_2}/Fi_{O_2} \leq 100$	Also includes Sp_{O2}/Fi_{O2} ratio Mild $235 < Sp_{O2}/Fi_{O2} \leqslant 315$ (if $Sp_{O2} \leqslant 97\%$) Moderate $148 < Sp_{O2}/Fi_{O2} \leqslant 235$ (if $Sp_{O2} \leqslant 97\%$) Severe $Sp_{O2}/Fi_{O2} \leqslant 148$ (if $Sp_{O2} \leqslant 97\%$)

[a] No minimum ventilatory setting defined for Pa_{O_2}/Fi_{O_2} data. *PAOP* , Pulmonary artery occlusion pressure.

[b] Based on oxygenation measured on a minimum of 5 cmH $_2$ O PEEP. For the mild classification only, oxygenation can also be assessed during non-invasive ventilation. For the moderate and severe classification the patient must be receiving intubated ventilatory assistance.

[c] For all severity categories of intubated ARDS, a minimum PEEP of 5 cm H $_2$ O is required. Patients may move from one category to another throughout their disease course.

For non-intubated ARDS- $Pa_{O2}/Fi_{O2} \leqslant 300$ mm Hg or $Sp_{O2}/Fi_{O2} \leqslant 315$ (if $Sp_{O2} \leqslant 97\%$) on HFNO with flow of ⩾30 L/min or NIV/CPAP with at least 5 cm H $_2$ O PEEP.
In resource-limited settings $Sp_{O2} : Fi_{O2} \leqslant 315$ (if $Sp_{O2} \leqslant 97\%$) with neither PEEP nor a minimum flow rate of oxygen required for diagnosis. HFNO, high-flow nasal oxygen. NIV/CPAP, Noninvasive ventilation/ Continuous positive airway pressure.

[d] ultrasound operator should be well trained in the use of ultrasound for identifying bilateral loss of lung aeration (e.g., multiple B lines and/or consolidations) and other ultrasound findings suggestive of noncardiogenic pulmonary edema (e.g., pleural line abnormalities).

Chest Radiograph and Chest Computed Tomography in Acute Respiratory Distress Syndrome

The intent of chest imaging is to exclude opacities due to pleural effusion, nodules, masses, collapse and pleural thickening; the infiltrate must be bilateral and consistent with pulmonary oedema. [2] Autopsy and chest radiographs of ARDS show a uniform process affecting both lungs. However, chest computed tomography (CT) [5] has demonstrated marked heterogeneity of lung inflation in ARDS with a dorsal, dependent increase in lung density, and relatively normal inflation of the ventral lung. In addition, CT can reveal otherwise undiagnosed pneumothorax, pneumomediastinum and pleural effusion. After the second week of mechanical ventilation, CT scans may demonstrate altered lung architecture and emphysematous cysts or pneumatoceles.

CT numbers or Hounsfield units can be assigned to each voxel (~2000 alveoli in a standard 10-mm slice). [5] These data can then be used to assess what proportion of a region of interest is non-aerated, poorly aerated, normally aerated or hyperinflated. Whole-lung CT allows (1) reconstruction of the upper and lower lobes (the middle lobe is difficult to separate), (2) the same section of the lung to be studied at different levels of inflation or PEEP (the lung also moves in a cephalo-caudad direction with respiration) and (3) a broader picture of the lung to be obtained (lung damage is heterogeneous in ARDS). However, whole-lung CT demands considerable exposure to ionising radiation, and different information, perhaps more pertinent to mechanical ventilation, is obtained from dynamic CT.

Clinical assessment of chest CT is discussed in Chapter 40 , and CT findings in ARDS are discussed under clinical management in this chapter.

Epidemiology

Estimates of the incidence and outcome from ARDS vary widely due to differences in the definitions used, case mix and local factors. Using the AECC definition, the Australian incidence was 34 per 100,000 for ALI and 28 per 100,000 for ARDS [6] ; while US estimates were 79 and 59 per

100,000, respectively [7] ; both much greater than many previous estimates. Data from 50 countries reports period prevalence of mild ARDS as 30.0%, moderate ARDS as 46.6%, and severe ARDS as 23.4%, respectively. ARDS represented 10.4% of intensive care unit (ICU) admissions and 23.4% of patients requiring mechanical ventilation. Clinical recognition of ARDS ranged from 51.3% in mild to 78.5% in severe ARDS. [8] However, the incidence of ARDS appears to be decreasing likely due to improvements in health care such as the use of protective ventilation strategies, reduced transfusion-related acute lung injury (TRALI) and better management of sepsis. [9]

For many years the mortality for ARDS was reported to be ~60%; data from 459 ICUs from 50 countries report hospital mortality as 34.9% for those with mild, 40.3% for moderate and 46.1% for severe ARDS. [8] Particular diagnostic groups such as multiple trauma have a lower mortality rate than other causes of ARDS, and patients with ARDS who have chronic liver disease, non-pulmonary organ dysfunction, sepsis or age greater than 70 years (hazard ratio, 2.5) have a higher risk of death. Clinical trial outcomes report relatively low mortality rates in the control arm in part due to the exclusion of patients with limited life expectancy; consequently, many factors need to be considered when assessing outcome prediction. More recently, the COVID-19 pandemic overwhelmed ICUs across the world, however, not all mortality was directly attributable to COVID-19–related lung injury [10] (see Chapter 49).

Patients at Risk for Acute Respiratory Distress Syndrome

About one-third of critically ill patients exposed to either a direct or indirect risk factor (Box 37.1) develop ARDS, most within 6–48 hours. Multiple risk factors such as low pH, chronic alcohol abuse or chronic lung disease substantially increase the incidence of ARDS in at-risk patients. Diabetes reduces the risk of developing ARDS. [11] Patient self-inflicted lung injury (P-SILI) is an emerging concept, whereby intense inspiratory efforts by spontaneously breathing patients, whether assisted or unassisted may exacerbate lung injury.

Box 37.1

Clinical risk factors for acute respiratory distress syndrome

DIRECT	INDIRECT
Pneumonia Aspiration of gastric contents Lung contusion Fat embolism Near drowning Inhalational injury Reperfusion injury Self-inflicted lung injury (P-SILI)	Non-pulmonary sepsis Multiple trauma Massive transfusion Pancreatitis Cardiopulmonary bypass

Fat Embolism Syndrome

Fat embolism syndrome (FES) is most commonly associated with long bone and pelvic fractures, and is more frequent in closed fractures than open fractures. Patients with a single long bone fracture have a 1–3% chance of developing FES, which increases with the number of fractures. Fat emboli usually result from fat globules entering the bloodstream or via the production of the toxic intermediaries of plasma-derived fat.

FES typically manifests 24–72 hours after the initial insult. [12] Affected patients develop a classic triad: hypoxaemia, neurological abnormalities and a petechial rash. Neurological abnormalities such as a confusional state followed by an altered level of consciousness develop in the majority of patients. The characteristic petechial rash may be the last component of the triad to develop. It occurs in only 20%–50% of cases and is found most often on the head, neck, anterior thorax, axillae and subconjunctiva. [13] The rash resolves in 5–7 days.

Early immobilisation of fractures reduces the incidence of FES, otherwise, treatment is the same as for ARDS.

Pathogenesis

Although it is well accepted that diffuse alveolar damage with (1) pulmonary oedema due to damage of the alveolocapillary barrier, (2) a complex inflammatory infiltrate and (3) surfactant dysfunction, [14] are essential components of ARDS, the sequence of events is uncertain and probably depends upon the precipitating insult and host response. For example in endotoxin-induced lung injury, hypoxaemia and reduced lung compliance occur well before the recruitment of neutrophils or an increase in lung weight due to an increase in permeability. [15] In addition, typical of early ARDS, surfactant turnover is dramatically increased prior to these changes. Furthermore, epithelial lining fluid sampled immediately following intubation in patients with ARDS has markedly increased concentrations of type III procollagen peptide, [16] suggestive of fibrosing alveolitis extremely early in the course of lung damage.

The Alveolocapillary Barrier

The normal lung consists of 300 million alveoli with alveolar gas separated from the pulmonary microcirculation by the extremely thin alveolocapillary barrier (0.1–0.2 µm thick). Since the endothelial pore size is 6.5–7.5 nm, and the epithelial pore size is almost one-tenth that at 0.5–0.9 nm, the epithelium is the major barrier to protein flux. [17] The surface area of the alveoli is estimated to be 50–100 m^{2} , which is made up predominantly of alveolar type I cells, with the metabolically active type II cells accounting for ~10% of the surface area. In turn, these cells are covered by the epithelial lining fluid with an estimated volume of 20 mL, ~10% of which is surfactant, the rest being filtered plasma water and low-molecular-weight proteins and a small number of cells, mainly alveolar macrophages and lymphocytes.

In ARDS the alveolocapillary barrier is damaged with bidirectional leakage of fluid and protein into the alveolus and leakage of surfactant proteins (SP) and alveolar cytokines into the plasma. Total protein content in bronchoalveolar lavage (BAL) fluid in ARDS is 20–100 times that found in both healthy subjects and ventilated subjects without cardiorespiratory disease.[18],[19] There is also disruption of the epithelial barrier, surfactant dysfunction and proliferation of alveolar type II cells as the progenitor of type I cells. Indirect causes of ARDS result in pulmonary endothelial injury, followed by recruitment of inflammatory cells and then epithelial damage, whereas direct causes of ARDS result in epithelial injury and secondary recruitment of inflammatory cells. The outcome of these processes must reflect a balance between repair and fibrosing alveolitis.

Cell Types Involved

The large surface area of pulmonary epithelium and endothelium, including the associated microcirculation, myofibroblasts and both alveolar macrophages and recruited neutrophils are all important components of ALI. BAL fluid has a marked increase in cell count; alveolar macrophage numbers are increased about twofold, but as a fraction of the cell count falls from around 90% to 20%–40% of the cell count due to a greater increase in neutrophils from around 1% to 50%–80% of the cell count. In addition, microparticles, tiny vesicles potentially derived from most of these cell types, are found in both BAL fluid and blood and may play an important role in both lung damage and repair.[20] A temporal trend towards more normal neutrophil and alveolar macrophage ratios in BAL fluid is associated with survival.

Table 37.2 summarises the role of these cells, alveolar epithelium and endothelium, chemokines and ions channels in the pathogenesis of ARDS.

Table 37.2

Mediators in Acute Respiratory Distress Syndrome[44]

Inflammation is usually a redundant process so that numerous mediators, including cytokines, chemokines, complement, reactive oxygen species, eicosanoids, platelet-activating factor, nitric oxide, proteases, growth factors and lysosomal enzymes, derived from a number of different cell types, play important roles in the pathophysiology of ARDS. As the alveolocapillary barrier becomes injured, these are no longer compartmentalised in the alveolus, and many of these proteins have been measured in blood as well as in the epithelial lining fluid. Care must be taken when interpreting these data, as immunological levels may not reflect biological activity, inhibitors or binding proteins may complex with the active protein or epitope and interfere with immunological detection, and the ultimate biological effect will depend upon a balance of pro-inflammatory and anti-inflammatory effects.

Of the pro-inflammatory mediators, TNF-α, IL-1β, IL−6 and IL-8 are the most important. However, even greater increases are found in their cognate receptors or antagonists such as the counter-regulatory cytokine IL-10 so that their biological impact is markedly reduced. [45] Blood or epithelial lining fluid levels are associated with mortality, but are rarely used clinically.

Resolution of Acute Respiratory Distress Syndrome and the Development of Fibrosing Alveolitis

Although histological evidence of fibrosing alveolitis (mesenchymal cells and new vessels in alveoli) is not usually found until at least 5 days following the onset of ARDS, elevated levels of type III procollagen peptide are found in the epithelial lining fluid soon after diagnosis [16] ; both oedema fluid and plasma levels are associated with mortality.

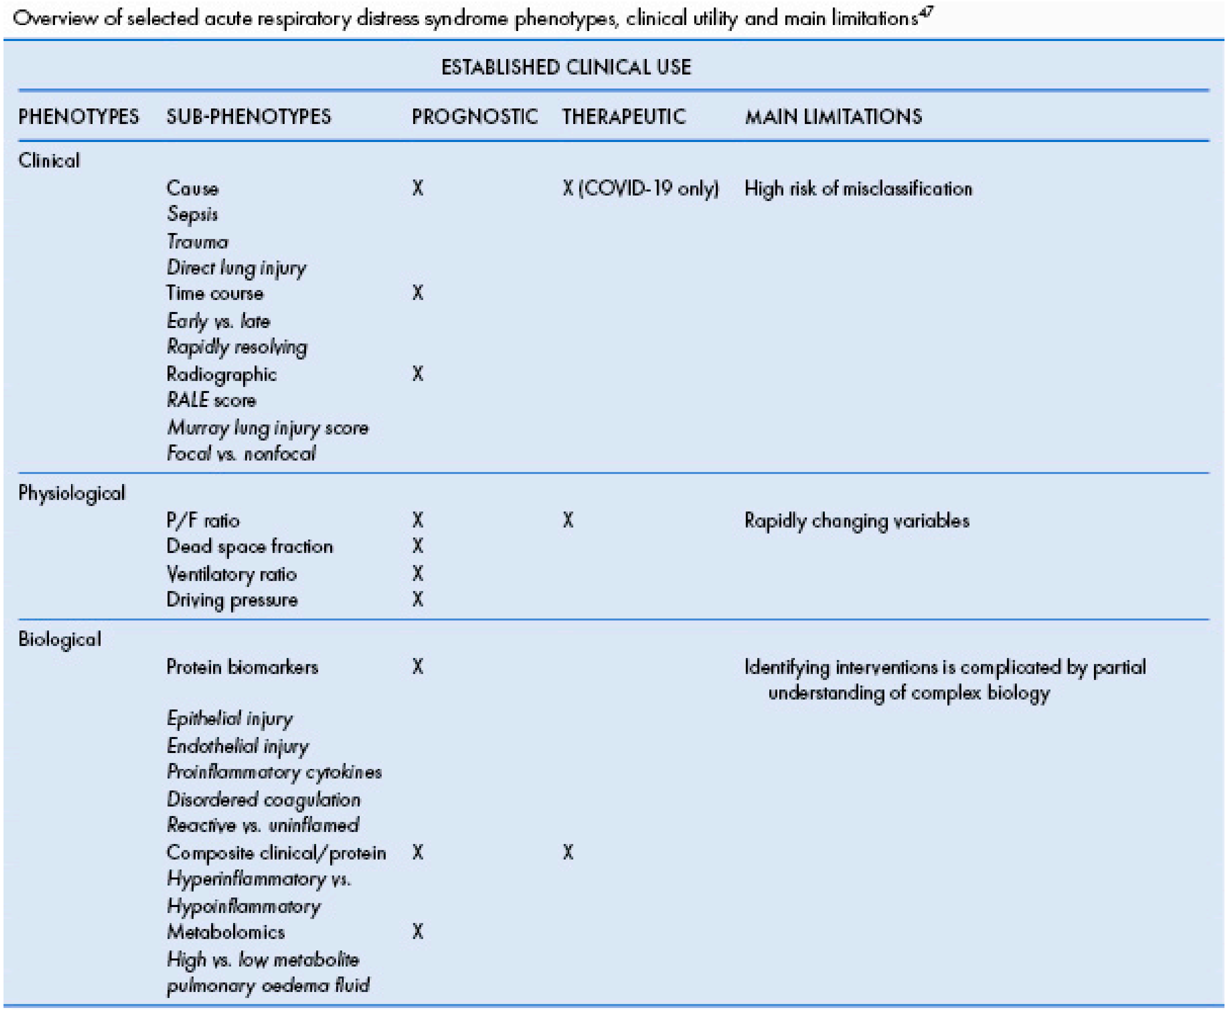
Clinical resolution of ARDS usually occurs provided that both the underlying cause is promptly and effectively treated, and that appropriate supportive care is provided. Alveolar oedema resolves with active transport of Na^+ by the type II cells followed by passive clearance of water through transcellular aquaporin channels; repair of the alveolocapillary barrier is associated with improved outcome. Type II cells proliferate and cover the denuded epithelium before differentiating into type I cells.

Both host response and the clinical course of ARDS influence lung remodelling in ARDS. Cross-talk between type II cells and alveolar macrophages, probably the M2 phenotype, along with epithelial-mesenchymal transition, a process where reactive oxygen species, hypoxia, TGF-β and mechanical stress lead to altered epithelial transcription, are central to interstitial responses. Epithelial cells assume characteristics of mesenchymal cells with loss of polarity, increased resistance to apoptosis and increased migration (into the interstitium) where they lay down a fibrotic matrix. [46]

ARDS Phenotypes [47]

Phenotyping ARDS (Table 37.3) using clinical, physiologic and biologic data has identified subgroups of patients with distinct clinical outcomes. Moreover, hyperinflammatory and hypoinflammatory biologic sub-phenotypes have demonstrated differential treatment responses in retrospective analyses of randomised controlled trials and cohort studies. [47-50] However, the progress in the field is challenged by insufficient data, lack of prospective validation, difficulties identifying clinically relevant sub-phenotypes that impact treatment outcomes and translating discoveries into effective therapies. [47] Real-time sub-phenotyping using novel assays and machine learning algorithms may enable phenotype-aware trials that hold the promise of identifying successful ARDS therapies. [51] Phenotyping ARDS may lead to a paradigm shift away from syndrome-based definitions towards treatable traits in future.

Table 37.3



Overview of selected acute respiratory distress syndrome phenotypes, clinical utility and main limitations[47]

		ESTABLISHED CLINICAL USE		
PHENOTYPES	SUB-PHENOTYPES	PROGNOSTIC	THERAPEUTIC	MAIN LIMITATIONS

Clinical Management of Acute Respiratory Distress Syndrome

The factors leading to ARDS must be promptly and appropriately treated. This includes diagnosis and treatment of infection with drainage of collections and appropriate antimicrobial agents, recognition and rapid resuscitation from shock, splinting of fractures and careful supportive care. Prevention of deep venous thrombosis, stress ulceration, nosocomial infection and malnutrition, often with enteral nutrition, must all be considered.

Early mobilisation of mechanically ventilated patients accompanied by appropriate levels of analgesia and sedation is feasible and safe, and offers shorter duration of ventilation, reduced delirium, ICU and hospital length of stay and improved mortality and functional outcomes.[52-54] However, two other randomised controlled trials[55], [56] have not shown benefit, and care must be taken not to exacerbate lung injury with premature spontaneous effort which may result in unintended increases in both transpulmonary airway and transmural hydrostatic pressure,[57] and asynchrony. For example use of neuromuscular blockers in the first 48 hours of mechanical ventilation in ARDS may reduce mortality,[58] possibly through prevention or reduction of these factors (see below).

Mechanical Ventilation

Acute hypoxaemic respiratory failure,[59] and an increase in the work of breathing, usually mandates mechanical ventilation (Table 37.4). The role of non-invasive ventilation in ARDS is contentious; there are no large definitive studies, and although some groups report encouraging results, these are usually in patients with mild ARDS.[60] Failure of non-invasive ventilation (NIV) is common, associated with greater complication rates and mortality, perhaps due to delayed intubation.[61-63] If non-invasive ventilation is considered in ARDS, it requires particular care (see Chapter 43).

Table 37.4

CT , Computed tomography.

The method and delivery of ventilatory support must take into account both the pathophysiology of ARDS and VILI. The ARDS Network randomised 861 ALI patients from 75 ICUs to receive either a tidal volume (V_T) of 12 or 6 mL/kg predicted body weight.[64] Mortality was reduced by

22%, from 40% to 31%, in the lower V_T group. There was a strict PEEP and Fi_{O_2} protocol, and patients were ventilated with assist-control ventilation to avoid excessive spontaneous V_T. Similar data with improved long-term survival are found in routine clinical practice [65]; however, it is the concept of lung protection rather than an exact V_T formula that is important.[66] As Hager and colleagues [67] found that lower V_T ventilation was protective across all quartiles of plateau pressure (P_{plat}) in the ARDS Network trial, with no safe upper limit of P_{plat}, it appears that the key variable is lower V_T rather than control of static airway pressure.

Avoidance of Overstretch and Inadequate Recruitment

The increase in dependent lung density found on chest CT, due to non-aerated and poorly aerated lung, reduces the volume of aerated lung available for tidal inflation ('baby lung'). Both PEEP and tidal recruitment will increase aeration of some of these air spaces, but a V_T that is not reduced in proportion to the reduction in aerated lung may lead to overstretch of aerated lung parenchyma and further diffuse alveolar damage. This is termed volutrauma, as increased airway pressure (P_{aw}) despite low V_T, due to decreased chest wall compliance, causes minimal damage compared with high V_T, high P_{aw} ventilation.[68] Atelectrauma refers to injury due to repeated opening and closing of air spaces during tidal inflation. Both volutrauma and atelectrauma result in alveolar inflammation and elevated alveolar cytokines (biotrauma), which may 'spill' into the systemic circulation.[69] However, as CT scans performed during ARDS Network protective ventilation show that tidal inflation occurs primarily in either normally aerated or overinflated compartments, with little tidal recruitment,[70] and PET-CT scans suggest that overinflation but not tidal recruitment is inflammatory,[71] overstretch appears to be the dominant mechanism causing VILI.

Overstretch

The normal lung is fully inflated at a transpulmonary pressure of ~25–30 cmH $_2$ O. Consequently, a maximum P_{plat}, an estimate of the elastic distending pressure, of 30 cmH $_2$ O has been recommended. [64] However, overinflation may occur at much lower elastic distending pressures (18–26 cmH $_2$ O). [68], [72]

The transpulmonary pressure may be lower than expected for a given P_{plat} in patients with a high chest wall elastance (e.g. obesity, abdominal compartment syndrome, after abdominal or thoracic surgery). While placement of an oesophageal balloon (see Chapter 38) allows measurement of the transpulmonary pressure and may allow better titration of PEEP, [73] it must be correctly placed, have an adequate occlusion pressure ratio, and measurements are preferably performed in a semi-sitting position to lift the mediastinum off the oesophagus. A noninvasive technique to measure partitioned lung mechanics with the use of PEEP-step method has been described but this requires further validation. [74]

Finally, inspiratory muscle contraction through reduction of intrapleural pressure lowers P_{plat}, potentially avoiding simple detection of an excessive transpulmonary pressure. This is particularly common when pressure support ventilation is used as a primary mode of ventilatory support; V_T that would produce an unacceptably high P_{plat} during mechanical ventilation will produce the same volutrauma during a spontaneous or supported mode of ventilation, and should be avoided. Provided the same V_T is generated, spontaneous ventilation does not reduce VILI compared to controlled ventilation, [75] and may exacerbate it. [57]

Static or dynamic volume-pressure curves or quantitative chest CT can be used to infer overinflation, though chest CT cannot determine overstretch. [5] Consequently, unless particular expertise is available, V_T limitation is currently the most practical approach.

Adequate PEEP

PEEP improves Pa_{O2} by recruiting alveoli and increasing end-expiratory lung volume. Because PEEP may reduce cardiac output by impairing venous return, Suter and co-workers suggested that at best PEEP the oxygen delivery (oxygen content × flow) was highest, and that this coincided with greatest compliance.[76] PEEP is commonly titrated to a particular Pa_{O_2}/FI_{O_2} ratio such as the ARDS Network protocol.[64] However, the amount of lung available for recruitment is extremely variable,[77] and does not differ comparing pulmonary with extrapulmonary ARDS.[78] Factors such as the duration, late ARDS being less recruitable and phenotype influence whether PEEP leads to alveolar recruitment, overinflation or a balance of both. Based on chest imaging, ARDS can be subdivided into focal, intermediate and diffuse phenotypes, with progressive increase in the amount of recruitable lung.[79,80] Applying ARDS Network ventilation to focal ARDS (about ⅓ of most cohorts) leads to high lung stress, with increased cytokine release, which can be ameliorated by using lower levels of PEEP.[81]

The lower inflection point of a volume-pressure curve has been used to set PEEP; early studies suggested that this reflected recruitment of collapsed alveoli. However, in patients with ARDS, recruitment occurs well above the lower inflection point, often along the entire volume-pressure curve and above the upper inflection point.[82,83] Concurrently, there is frequent evidence of overstretching and hyperinflation on CT scans[5,84] or dynamic volume-pressure analysis.[72] Meta-analysis of major clinical trials using protective V_T and comparing higher and lower PEEP scales[85] did not find an overall improvement in outcome with higher PEEP, although rescue therapies were required less often. However, patients with mild ARDS tended to have worse outcomes with higher PEEP, and those with moderate to severe ARDS had better outcomes.

These data suggest individual patients may benefit from a tailored approach. Although routine CT analysis has been advocated by some, it is cumbersome and has not been shown to influence outcome; non-invasive bedside alternatives are under investigation. Consequently, PEEP titration is often a compromise aiming to minimise both atelectrauma and volutrauma.[86] Reasonable approaches to PEEP titration include (1) the use of a scale similar to the ARDS Network protocol, (2) titration of PEEP to Pa_{O_2} aiming for a PEEP of ~15 cmH_2O, or (3) measuring elastic mechanics at the bedside. Consistent with Suter's early observation, [76] both nadir elastance after a recruitment manoeuvre, [87] or minimal change in driving pressure (see also Chapter 38), offer bedside methods to individualise PEEP.

In patients at risk for ARDS, prophylactic PEEP (8 cmH_2O) was not protective. [88]

Airway opening pressure

Airway closure phenomenon has been reported in one-third of patients with moderate/severe ARDS. [89] The airways are totally closed until a sufficiently high airway opening pressure (AOP) is reached with reopening pressure anywhere between 6 and 20 cm H_2O. Thus, lung inflation begins when the airway pressure overcomes the AOP. If PEEP is set below the AOP, this may bias the assessment of respiratory mechanics. [90] Moreover, cyclic opening and closing of small airways may also occur and promote ventilator-induced lung injury and development of denitrogenation atelectasis in zones that are only intermittently reopened. [89] Measurement of AOP during mechanical ventilation requires a low-flow insufflation (i.e., 5 L/min) [89] to make the resistive component of airway pressure negligible, though other methods without the need for low-flow insufflation are also described. [91] Measuring AOP is important to look for a potential airway closure in ARDS in order to customize mechanical ventilation.

Driving pressure

This is defined as the difference between the end-inspiratory plateau pressure and the total PEEP. In a meta-analysis of nine randomised controlled trials of protective ventilation strategies (lower V_T, lower P_{plat} and higher PEEP), Amato and colleagues identified the driving pressure as the variable most robustly associated with improved outcomes. [92] Although the driving pressure is an appealing and intuitive way of thinking about minimising lung stress, protocols examining this method need to be prospectively tested using patient-centred outcomes to exclude indirect association as the basis for these findings. This is important as in a re-analysis of pooled data from five randomised trials, dominated by the

ARDS Network ARMA trial, it was demonstrated that the impact of tidal volume limitation on mortality varied considerably according to baseline elastance with no effect seen when elastance was low. [93]

Measuring dynamic driving pressure in assisted spontaneous ventilation with the use of an expiratory hold manoeuvre (measuring occlusion pressure (P_{occ})) [94] has been proposed but its role in preventing self-induced lung injury requires further investigation.

Mechanical Power

This concept is based on the amount of energy transferred from the ventilator to the respiratory system. During mechanical ventilation, energy changes from electrical to potential, kinetic and heat energy as the pressure is generated to move air into the lungs. It is this transfer of energy that may affect the lung parenchyma to make structural changes at the cellular and tissue level that may contribute to the lung injury. [95-98] This energy transferred from the ventilator to the lungs per individual breath per unit time is called mechanical power.

The use of mechanical power as a ventilator parameter in patients with ARDS does make physiological sense as it combines many of the factors that contribute to VILI (flow, pressure and repetitive cycling), [95] but currently, there is there are only associations between high mechanical power and poor clinical outcomes and there is lack of prospective randomised control data. Furthermore, there is no set cut-off of accepted safe level of mechanical power and there is variability in its calculation. Finally, its utility in addition to the current used low tidal volume and safe driving pressures required further investigation.

Ventilatory ratio

Ventilatory ratio is defined as [minute ventilation (mL/min) × $PaCO_2$ (mm Hg)]/(predicted body weight × 100 × 37.5); it correlates well with physiological dead space in ARDS, [99] and higher values at baseline are associated with increased risk of adverse outcomes. These results are promising for the use of ventilatory ratio as a simple bedside index of impaired ventilation in ARDS but require further validation.

Recruitment manoeuvres and open lung ventilation

Open lung ventilation refers to an approach where the lung is maximally recruited, usually through application of higher PEEP, recruitment manoeuvres and efforts to minimise derecruitment. In theory, increased lung volume will result in less tidal overinflation and improved outcome. However, despite alveolar recruitment with open lung ventilation, overinflation may occur in previously normally aerated lung.[100] The recruitment manoeuvre may be followed by a marked improvement in oxygenation; however, this is not a consistent finding, and hypotension may occur due to reduced venous return if there is inadequate fluid loading.

During a typical recruitment manoeuvre, a high level of continuous positive airway pressure (CPAP) (30–40 cmH$_2$O) is applied for 30–40 seconds in an apnoeic patient, followed by return to a lower level of PEEP and controlled ventilation. This may be suboptimal; an alternative, for example is a staircase recruitment manoeuvre where airway pressure is sequentially increased every 2 minutes, and then decreased until oxygenation deteriorates.[101] A number of small trials have shown improvement in oxygenation following recruitment manoeuvres; however, the largest clinical trial[102] failed to show an effect. Grasso and colleagues[103] found that recruitment manoeuvres were effective in improving oxygenation only early in ARDS and with lower levels of baseline PEEP, which probably explains the variable responses reported. Furthermore, there is evidence of increased mortality with the use of lung recruitment and titrated PEEP when compared to low PEEP,[104] however, there was high mortality rate in both study groups and the results may lack external validity to other settings.

In addition to physical recruitment of alveoli, lung stretch above resting V_T is the most powerful physiological stimulus for release of pulmonary surfactant from type II cells. This is associated with a decrease in lung elastance and improved Pa_{O_2} in the isolated perfused lung,[105] and is a possible explanation for the improvement in oxygenation, recruited lung volume and elastance reported with the addition of three sigh breaths in patients with ARDS.[106] Similarly, in models of lung injury, biologically variable or fractal V_T is associated with less lung damage with lower alveolar levels of IL-8,[107] improved oxygenation and lung elastance and greater surfactant release.[108] These data caution against monotonous low V_T ventilation, and suggest that intermittent or variable lung stretch may reduce lung injury.

Mode of Ventilation

Non-invasive ventilation should not be routinely used in ARDS (see Chapter 43) and most patients require intubated mechanical ventilation. Following intubation, controlled ventilation allows immediate reduction in the work of breathing, and application of PEEP and a controlled FI_{O2} . Later in the clinical course, assisted or supported modes of ventilation may allow better patient-ventilator interaction (see Chapter 42), and possibly improved oxygenation through better V / Q mismatch as a result of diaphragmatic contraction.[109] Withdrawal or weaning from mechanical ventilation is discussed in Chapter 42 .

An advantage of assist-control ventilation (as used in the ARDS Network study) is that spontaneous effort generates a controlled V_T . However, the fall in airway pressure during triggered ventilation (e.g. assist control or supported ventilation) can result in worse lung injury than controlled ventilation in early ARDS, although a beneficial effect can be seen when the underlying lung injury is less severe.[110] This may be due to greater transpulmonary and transmural pressure changes, and heterogeneity of lung inflation. Care should also be taken with synchronised intermittent mandatory ventilation (SIMV), particularly if pressure support is added to SIMV, as excessive V_T may occur during supported breaths.

There is an increasing tendency to use pressure-controlled ventilation (PC) or pressure-regulated volume control (PRVC), as P_{pk} is lower than volume-controlled (VC) ventilation with a constant inspiratory flow pattern. However, the decelerating flow pattern of PC or PRVC means that most of the resistive pressure (P_{res}) during inspiration is dissipated by end inspiration, which is in contrast to VC with a constant inspiratory flow pattern where P_{res} is dissipated at end inspiration. Consequently, with PC and PRVC $P_{pk} \approx P_{plat}$ which is the same as P_{plat} during VC.[111] Oxygenation, haemodynamic stability and mean airway pressure are no different between PC and VC and a moderate-sized randomised study found no difference in outcome.[112] However, there may be differences in lung stress due to greater viscoelastic build-up with VC.[113]

Inverse ratio ventilation, often together with PC, has been used in ARDS. However, when $PEEP_i$ and total PEEP are taken into account, apart from a small decrease in $PaCO_2$, there are no advantages with inverse ratio ventilation. Mean airway pressure is higher with a greater risk of both haemodynamic consequences, and regional hyperinflation.[111] Consequently, an inspiratory to expiratory ratio greater than 1:1 is recommended.

A number of other modes of ventilation (see Chapter 42), including airway pressure release ventilation (APRV) and high-frequency oscillation (HFO) have been proposed for use in ARDS.

Randomised clinical trials have not shown improved outcomes with APRV,[114] despite potential physiological benefits. The small V_T used with HFO, although appealing, may increase hospital mortality when compared with a ventilation strategy of low tidal volume and high PEEP.[115]

Use of personalisation of mechanical ventilation based on lung morphology (focal vs non-focal ARDS) has been examined and although did not decrease mortality, possibly because of the high number of misclassification of patients, a ventilator strategy misaligned with lung morphology substantially increases mortality.[116] Whether improvement in ARDS phenotyping can decrease mortality should be assessed in a future clinical trial.

P-SILI may occur in spontaneously breathing patients receiving assisted ventilation via an endotracheal tube or non-invasive ventilation or in the absence of ventilatory support. This is also relevant in patients weaning from control to spontaneous mode (pressure support) ventilation. This may result from intense inspiratory effort, resulting in both excessive swings in transpulmonary pressure (i.e. lung stress) contributing to regional overinflation, and abnormal increases in transvascular pressure, favouring negative-pressure pulmonary oedema. There is also a possibility of an intra-tidal shift of gas between different lung zones, generated by different transmission of muscular force (i.e. pendelluft), diaphragm injury and increased lung inflammation. This is more likely with vigorous spontaneous respiratory efforts and in those with severe ARDS. Hence the patient's respiratory effort during spontaneous modes should be monitored. However, concerns about P-SILI must be balanced against the harms from prolonged controlled ventilation, over-sedation and paralysis, when allowing patients to breathe spontaneously.

Use of venovenous extracorporeal membrane oxygenation (ECMO) has been investigated in patients with ARDS and shown to both increase survival and minimise severe disability, and to be cost-effective. [117] However, caution must be taken in extrapolating these results, as almost a quarter of those randomised to the ECMO group did not receive it, and control patients were not transferred to the single trial hospital. More recently, results from the EOLIA trial [118] provide inconclusive support for the benefit of ECMO in severe ARDS. The early initiation of ECMO did not improve 60-day mortality compared to standard care in patients, however, study also suggests a possible clinical benefit from ECMO over standard care, especially if used early rather than late. Moreover, the standard therapy arm, which included proning and use of neuromuscular blockers, had a high rate of failure requiring rescue with ECMO (large number of crossovers in the control arm). Currently, vv-ECMO is sometimes used as a rescue therapy (see Chapter 50).

Target Blood Gases

As discussed earlier, there are many variables that need to be considered when choosing target blood gases in ARDS. For example, if a patient also has a traumatic brain injury, it may be inappropriate to accept hypercapnia.

Oxygenation targets and FI_{O2}

There must be a compromise between the major determinants of oxygenation, including the extent of the poorly or non-aerated lung, hypoxic pulmonary vasoconstriction and mixed venous oxygen saturation and the target Pa_{O2} or Sp_{O2} . A recent trial reported lower ICU mortality with target Pa_{O2} values of 70–100 mm Hg versus values up to 150 mm Hg. [119] Because positive-pressure ventilation may reduce cardiac output, it is also important to consider tissue oxygenation. However, a conservative target of Sp_{O_2} between 91% and 96% or Pa_{O_2} of 60 mm Hg did not lead to any further clinical benefit.[120], [121] Moreover, in patients with ARDS, early exposure to a conservative oxygenation strategy with a Pa_{O_2} between 55 and 70 mm Hg did not increase survival at 28 days and might be associated with harm.[122] Larger studies are awaited.[123] However, a strategy targeting permissive hypoxaemia ($\mathrm{Sp}_{O_2} \leq 88\%$ or $\mathrm{Pa}_{O_2} < 60$ mm Hg) should be avoided. This is particularly important as there are concerns about hidden hypoxemia (i.e. $\mathrm{Sp}_{O_2} \geq 88\%$ (measured by pulse oximetry) but SaO_2 <88% (measured by arterial blood gas)) according to patients' race and ethnicity.[124] However, high FI_{O_2} may also cause tissue injury, including diffuse alveolar damage. The balance between increased airway pressure and FI_{O_2} is unknown, but high FI_{O_2} is generally regarded as being less damaging.[125] In part this is because diffuse alveolar damage itself protects the lung against hyperoxia, perhaps through prior induction of scavengers for reactive oxygen species.[126] A reasonable compromise is to start ventilation at a Fi_{O_2} of 1 and to titrate down, aiming for a Fi_{O_2} of <0.6.

Carbon dioxide target

Low V_T strategies will result in elevations in PaCO_2 unless minute ventilation is augmented by an increase in respiratory rate. The ARDS Network protocol aimed at normocapnia, with a maximum respiratory rate of 35, to minimise respiratory acidosis.[73] This exposes the lung to more repeated tidal stretch and may result in dynamic hyperinflation due to a shortened expiratory time.[127] In addition, allowing PaCO_2 to rise above normal may not be harmful in many patients.

If hypercapnic acidosis occurs slowly, intracellular acidosis is well compensated and the associated increase in sympathetic tone may augment cardiac output and blood pressure. Although respiratory acidosis may worsen pulmonary hypertension and induce myocardial arrhythmias, these effects are often small, particularly if there has been time for metabolic compensation. In addition, in an ischaemia-reperfusion model of ARDS, therapeutic hypercapnia reduced lung injury and apoptosis,[128] but was harmful in prolonged untreated pneumonia.[129]

Extracorporeal CO_2 removal technologies may facilitate further lowering of ventilator stretch, allowing dissection of the contribution of CO_2 and tidal stretch to lung injury or protection in ARDS. Feasibility and safety of extracorporeal CO_2 removal ($ECCO_2R$) to enhance protective ventilation in ARDS has been investigated,[130] and use of $ECCO_2R$ to facilitate ultra-protective ventilation was found to be feasible. However, there was a high number of adverse events in this study; the unclear benefit of ultra-low tidal volume ventilation argues against use of $ECCO_2R$ in ARDS outside of a clinical trial.

Finally, hypercapnia should be avoided in patients with or at risk from raised intracranial pressure.

Non-Ventilator Management

Prone Posture

In patients with severe ARDS, early application of prolonged prone-positioning sessions significantly decreased 28- and 90-day mortality.[131] Notably, the study entry Pa_{O2}/FI_{O2} ratio was less than 150 (20 kPa %), enrolment was within 36 hours of commencing mechanical ventilation, and the ICUs had more than 5 years of experience in managing ARDS patients with prone positioning. The mechanisms involved include increased chest wall elastance, recruitment of dorsal lung, with concurrent ventral collapse; however, perfusion is more evenly distributed leading to better V/Q matching[132,133] and unloading the right ventricle.[134] While this meta-analysis provided similar results,[135] a number of prior studies did not find clear evidence of benefit.[136,137] Moreover, the study did not control for lung heterogeneity (ARDS phenotype), or co-interventions (did not control or report fluid balance, or cumulative dose of catecholamines), and had baseline imbalances of neuromuscular blockers and a high rate of cardiac arrest. Even with the COVID-19 pandemic, where the use of prone position (including self-proning in unintubated patients) become more common,[138] the use of prone positioning still remains sporadic and more studies are needed.

Manipulation of the Pulmonary Circulation

iNO and aerosolised prostacyclin (PGI_2) may be used to reduce pulmonary shunt and right ventricular afterload by reducing pulmonary artery impedance. When hypoxic pulmonary vasoconstriction is active, there is redistribution of pulmonary blood flow away from the poorly ventilated dependent areas to more normally ventilated lung leading to an increase in Pa_{O2}. Both iNO and PGI_2 are delivered to well-ventilated lung; both vasodilate the local pulmonary circulation and augment the effects of hypoxic pulmonary vasoconstriction. Intravenous almitrine is a selective pulmonary vasoconstrictor that reinforces hypoxic pulmonary vasoconstriction and, although this may improve oxygenation alone, there is a synergistic effect with iNO.

Inhaled NO or PGI_2 may also be used to reduce right ventricular afterload; however, a consequent increase in cardiac output is rare in ARDS. Intravenous PGI_2 will improve cardiac output in ARDS, though there is non-specific pulmonary vasodilation with increased blood flow through poorly ventilated lung zones, resulting in deterioration in oxygenation.

Inhaled Nitric oxide

Nitric oxide is an endothelium-derived smooth muscle relaxant. It also has other important physiological roles including neurotransmission, host defence, platelet aggregation leucocyte adhesion and bronchodilation. Doses as low as 60 parts per billion iNO may improve oxygenation; however, commonly used doses in ARDS are 1–60 parts per million, with the higher doses required for reduction in pulmonary artery pressure. A rise in Pa_{O_2} exceeding 20% is generally regarded as a positive response; iNO should be continued at the minimum effective dose.

Inhaled NO may be delivered continuously or using intermittent inspiratory injection. Delivery is usually in the form of medical grade NO/N_2, and this should be adequately mixed to avoid delivery of variable NO concentrations. It is recommended that inspiratory NO and NO_2 concentrations are measured, either by an electrochemical method or by chemiluminescence. The electrochemical method is accurate to 1 ppm, which is adequate for clinical use and is less expensive. Local environmental levels of NO and NO_2 are low and predominantly influenced by atmospheric concentrations; however, it is still common practice to scavenge expired gas. Binding to haemoglobin in the pulmonary circulation rapidly inactivates NO, and systemic effects are reported only following high concentrations of iNO. Systemic methaemoglobin levels may be monitored, and are generally less than 5% during clinical use of iNO, but they should be compared with a baseline level. Nitric oxide may cause lung toxicity through combination with oxygen free radicals, and through metabolism of NO to NO_2; however, these do not appear to be major clinical problems. However, there are concerns about delayed resolution of pulmonary oedema with its usage. [139]

Only 40%–70% of patients with ARDS have improved oxygenation with iNO (responders), and this is likely due to active hypoxic pulmonary vasoconstriction in the remainder. Clinical trials [140] have shown no improvement in mortality or reversal of ARDS and an increased risk of renal impairment. However, iNO transiently improves oxygenation (as compared with placebo or no iNO), which has been sustained beyond 12–24 hours in some trials. As constant dosing of iNO leads to both increased sensitivity and apparent tachyphylaxis, [141] subsequent investigation needs to consider different dose regimens. Currently, iNO cannot be recommended for routine use in ARDS; however, in some patients with severe hypoxaemia, iNO will provide temporary rescue.

Inhaled prostacyclin

PGI_2 (up to 50 ng/kg per minute) improves oxygenation as effectively as iNO in ARDS patients, [142] and may reduce pulmonary hypertension. It is continuously jet nebulised due to its short half-life (2–3 minutes). Potential advantages include increased surfactant release from stretched type II cells, avoidance of the potential complications of iNO, and minimal toxicity. However, PGI_2 is dissolved in an alkaline glycine buffer, which alone can result in airway inflammation, and the sticky nature of the aerosol can result in expiratory valve obstruction and requires active monitoring. Iloprost is a derivative of PGI_2 with similar activity, a longer duration of action, without an alkaline buffer. Neither agent has been shown to improve outcomes in ARDS patients.

Conservative fluid balance

Conservative fluid balance has been shown to decrease the length of mechanical ventilation when compared with liberal fluid balance in patients with ARDS, [143] although in a small number of patients who were followed up (30% of eligible survivors), it was associated with adverse neurocognitive outcome. [144] An intermittent approach between conservative and liberal fluid balance offers [145] solutions but has to be examined in larger prospective trials. A positive sodium balance is associated with respiratory dysfunction independent of fluid balance, [146] and future trials need to control for sodium balance in addition to fluid balance in patients with ARDS. Recent research suggests that inflammatory phenotypes may differ in their fluid responsiveness. Future studies further refining ARDS phenotypes and their associated differential responses to fluid administration may help guide optimal fluid management strategies in ARDS. [47]

High Flow Oxygen

Use of high-flow humidified oxygen through nasal cannula (HFNC) has become common in patients with acute hypoxaemic respiratory failure. As the gas flow rate (15–60 L/min) is close to the subject’s inspiratory flow rate, there is little dilution of the inspired oxygen fraction. Additional mechanisms include flow-dependent continuous positive airway pressure with increased end-expiratory lung volume, and washout of upper airway carbon dioxide leading to decreased physiological dead space, with both contributing to reduce the work of breathing. Compared to standard oxygen or NIV, HFNC reduced intubation in patients with hypoxic respiratory failure. [147] However, as the rate of intubation was high (38%), caution should be used as delayed intubation can lead to poor outcomes. [148] The role of HFNC in ARDS is uncertain and endotracheal intubation and lung protective ventilation should not be delayed. [149]

Neuromuscular blocker

The ACURASYS trial in 2010 examined neuromuscular blockade in patients with severe, early ARDS and found that both the adjusted 90-day survival rate and time of the ventilator were greater in the cisatracurium group as compared with the placebo group.[58] This was despite the fact that variables commonly used to assess the propensity for VILI (e.g. plateau pressures and tidal volumes) did not differ significantly between the cisatracurium group and the placebo group, although reduced asynchrony and adverse effects attributable to triggering ventilation cannot be excluded.[57,150] However, more recently a larger study examining deep sedation combined with an infusion of cisatracurium did not improve 90-day mortality when compared with a light sedation strategy in a cohort of patients recruited early in the course of moderate-to-severe ARDS.[151] As there are concerns about long-term muscle weakness[152] its routine use in ARDS patients cannot be recommended except in the management of patient ventilator asynchrony.

Surfactant Replacement Therapy

Surfactant dysfunction is an important and early abnormality contributing to lung damage in ARDS.[14,153] Pulmonary surfactant reduces surface tension promoting alveolar stability, reducing work of breathing and lung water. In addition, surfactant has important roles in lung host defence. Reactive oxygen species, phospholipases and increased protein permeability lead to inhibition of surfactant function. In addition, composition is abnormal, and turnover markedly increased. VILI is difficult to demonstrate without surfactant dysfunction.[153] Consequently, there has been considerable interest in exogenous surfactant replacement therapy.

Exogenous surfactant therapy has an established role in neonatal respiratory distress syndrome. In paediatric ARDS, particularly due to direct lung injury, clinical trials have been promising. However, in adults, results have been disappointing; subgroup analysis of recombinant SP-C-based surfactant administered intratracheally improved oxygenation in direct ARDS without an improvement in mortality.[154] However, subsequent research in this cohort failed to confirm these data, perhaps owing to inactivation of the surfactant during administration.[155]

Glucocorticoids

Glucocorticoids may have a role in ARDS through their reduction of the intense inflammatory response and their potential to reduce fibroproliferation and collagen deposition, by faster degradation of fibroblast procollagen mRNA. Preventative steroids increase the incidence of ARDS and, although there may be a greater number of ventilator-free days and the possibility of a reduction in mortality, [156], [157] neuromuscular complications, immunosuppression, superadded infection and higher blood glucose levels and increased mortality when steroids are administered more than 13 days after the onset of ARDS, [158] argued against their routine use in the past. However, a recent Spanish study showed that in patients with early but established moderate-severe ARDS the use of dexamethasone in addition to standard care, significantly increased the number of ventilator-free days and significantly reduced mortality. [159] Moreover, in patients hospitalised with COVID-19, the use of dexamethasone resulted in lower 28-day mortality among those who were receiving either invasive mechanical ventilation or oxygen alone. [160] This recent evidences indicated that future trials with the use of corticosteroids in ARDS patients should be enriched with ARDS phenotype to identify the subgroup of patients who would benefit the most. [47]

Statins

Statins not only inhibit cholesterol synthesis in the liver but also decrease production of multiple downstream signalling molecules, which may be the aetiology of their anti-inflammatory effects. [161] They have shown a decrease in inflammation and lung injury in murine and human models, suggesting a role in ARDS. [162] Although the clinical trials have been negative, [163] there is evidence of a differential response and a suggestion of its possible value in hyperinflammatory ARDS phenotype, [164] and this requires further evaluation.

Mesenchymal Stromal Cells

Preclinical studies suggest that human mesenchymal stromal cells (MSCs) may attenuate inflammation, enhance resolution of lung injury and facilitate bacterial clearance, and thus hold promise for ARDS. [161], [165] Preliminary trials in patients with moderate-to-severe ARDS have demonstrated that MSCs are safe and well-tolerated. [165-167] Although these initial reports are promising, further research is needed to determine the efficacy of MSCs, and clinical trials are ongoing.

Other Pharmacological Therapies

Numerous other therapies including cytokine antagonism, non-steroidal anti-inflammatory drugs, scavengers of reactive oxygen species, lisofylline, [168] Vitamin C [169] and interferon (IFN) β-1a [170] have been trialled without success. The complex balance of inflammation and repair in ARDS, and the critical additional damage secondary to VILI, may explain these results. However, studies in less heterogeneous groups with minimisation of VILI using standardised ventilation protocols, together with a growing understanding of ARDS, offer potential pharmacological therapies. Many promising therapeutic options such as TRPV4 antagonism, IL-1α/β inhibitor, [171] stem cell therapy and enriched trials with the use of ARDS phenotypes are currently under investigation. Therapies focusing on suppressing cytokine activity with the use of interleukin-6 antagonists, Janus kinase inhibition, have shown some success, in patients with COVID lung injury [172] and these might be examined in a broader cohort of ARDS patients.

Pulmonary Function in Survivors

Respiratory function continues to improve after discontinuation of mechanical ventilation, and usually returns towards normal by 6–12 months. [173], [174] Although a variety of abnormal pulmonary function tests may be found, impaired diffusing capacity is the most common. This is rarely symptomatic, but occasional patients have severe restrictive disease, and this is correlated with their cumulative lung injury. [174]

Quality of Life in Survivors

Compared with disease-matched ICU patients who do not develop ARDS, patients with ARDS have a more severe reduction in both pulmonary and general health-related quality of life. [175] Many patients have a reduction in exercise tolerance that may be attributable to associated critical illness neuropathy and myopathy; nerve entrapment syndromes, contractures, postural hypotension and heterotopic calcification may play a role in a minority. [173] When followed for 5 years in a young and severe cohort (median age 45 years) with relatively few prior co-morbidities, there was persistent functional impairment with little improvement after 12 months. [176] Depression, anxiety and post-traumatic stress disorder are also common (20%–50% of survivors). Finally, most survivors have cognitive impairments such as slowed mental processing, or impaired memory or concentration, and these correlate with the duration of ventilation, hyperglycaemia and variability in blood glucose, and the period and severity of desaturation less than 90%. [177, 178] In an analysis of survivors of the ARDS Network Fluid and Catheter Trial (FACTT), [143] Mikkelsen and co-workers [144] found that over half the subjects suffered from cognitive dysfunction and from psychological disability, and that these parameters were associated with lower Pa_{O_2}, enrolment in the restrictive fluid arm and hypoglycaemia. Taken together these data caution against permissive hypoxaemia as a strategy (especially with concerns of hidden hypoxaemia) [124] to reduce ventilator-induced lung injury (VILI), and suggest that quality of survival is an important additional outcome for clinical trials.

Respiratory monitoring

Andrew Bersten and Thomas J. Morgan

History and respiratory examination are particularly important in critically ill patients. Attention should be directed at the respiratory rate (f), the most poorly documented vital sign, the quantity and nature of sputum and evidence of excessive inspiratory and/or expiratory pleural pressure changes and effort, which include accessory muscle use, tracheal tug, supraclavicular and intercostal indrawing, paradoxical abdominal movement (which is suggestive of diaphragmatic fatigue), [1] and pulsus paradoxus. During spontaneous ventilation, an excessive fall in blood pressure during inspiration (>10 mm Hg) is found both in low-output states such as cardiac tamponade, cardiogenic shock pulmonary embolism, hypovolaemic shock and in acute respiratory failure. The fall in pleural pressure during spontaneous inspiration has a curvilinear relationship with the fall in blood pressure. However, as there is marked variation between individuals, [2] pulsus paradoxus is most useful as a trend. A reduction in the degree of paradox may reflect improvement with a fall in the negative pleural pressure needed for ventilation or may reflect respiratory muscle insufficiency, and an inability to generate the same negative pleural pressure.

Additional information can be gained from data on gas exchange and respiratory mechanics. This chapter will focus on tests of respiratory function that are directly relevant to critically ill patients.

Gas Exchange

Oxygen

Data are sampled at waypoints down the oxygen cascade, from inspired gas to intracellular organelles.

Inspired Gas

The inspired oxygen partial pressure (PiO_2) can be adjusted to mitigate hypoxia and prevent hyperoxia. The PiO_2 of humidified gas is the product of the fraction of inspired oxygen and (FiO_2) the barometric pressure (BP) minus the saturated vapour pressure (SVP) of water (47 mm Hg at 37°C).

$$\mathrm{PiO_2}(\mathrm{mm\,Hg}) = \mathrm{FiO_2} \times (\mathrm{BP} - \mathrm{SVP}) \qquad \textbf{(38.1)}$$

Monitoring includes:

- Gas supply and ventilator input pressures.
- Oxygen concentrations (paramagnetic analysers) in the inspiratory module and circuit.

Transfer of Inspired Gas to Alveoli

Signs there is open communication between the oxygen delivery system and pulmonary alveoli:

- No evidence of upper airway obstruction.
- Expired tidal and minute volumes and ventilator airway pressures within correctly set alarm limits.
- Capnograph waveforms are present and appropriate.

Alveolar Gas

The PO_2 in individual lung units varies considerably. On 100% oxygen, it can range from <40 mm Hg to >600 mm Hg. Measured end-tidal PO_2 and end-tidal O_2 fractions contribute data to some gas exchange monitoring modalities.[3,4]

Distribution of Alveolar Ventilation

Can be tracked by:

- Observing chest movement, auscultating air entry and examining chest radiographs.
- Electrical impedance tomography (as discussed later).
- CT scanning.
- O_2 washout curves.[5]
- Functional imaging by magnetic resonance imaging (MRI)[6,7] with an expanding role in machine learning/artificial intelligence.[8]

Matching Ventilation and Perfusion

The estimated mean alveolar count in the adult human lung is 480×10^6 (range: 274×10^6 to 790×10^6),[9] organised into approximately 100,000 lung units (acini) with some collateral communication.[10] Equilibration between alveolar gas and mixed venous blood occurs across an ‘air-blood barrier’ measuring ~0.1 µm in its thinnest sections.[11]

To model gas exchange in this complex structure, John West applied a spread of ventilation/perfusion (V/Q) ratios to a representative group (usually 50) of notional lung units operating in parallel without collateral ventilation, each consisting of a single alveolus linked exclusively to a single pulmonary capillary.[12]

The Multiple Inert Gas Technique (MIGET)

MIGET is a diagnostic research tool based on the West model.[10,13,14] Although technical challenges limit routine clinical usage, MIGET evaluations have been instructive, often extending beyond simple ‘log normal’ distributions. Examples include [14–17] :

- Q ‘tails’ or ‘shoulders’ projecting to the low V_A / Q side in the ageing lung.
- Bimodal distributions, for example in acute respiratory distress syndrome (ARDS) and asthma.

The Three-Compartment Model

The precursor of West’s approach was the three-compartment lung model of Riley and Cournand. [18], [19] Venous admixture and A-a gradient calculations (see later) are based on this ultra-minimalist model.

Compartments are:

- ‘Ideal’, with matched ventilation and perfusion ($V_i / Q = 1$)
- ‘Venous Admixture’, perfused but not ventilated ($V_i / Q = 0$)
- ‘Dead Space’, ventilated but not perfused ($V_i / Q = \infty$)

The PO_2 in the ‘ideal compartment (PAO_2) is calculated from the alveolar gas equation:

$$\mathrm{PAO_2 = PiO_2 - (1 - FiO_2 \times (1 - R)) \times PaCO_2/R} \tag{38.2}$$

$PaCO_2$ is arterial PCO_2 . PiO_2 is calculated as in Eq. (38.1) . R is the respiratory exchange ratio, usually assumed to be 0.8. A common approximation is:

$$PAO_2 = PiO_2 - PaCO_2/0.8 \tag{38.3}$$

Transfer from Alveoli to Arterial Blood

In critical illness MIGET analysis has revealed right to left shunt ($V_i/Q = 0$) and low V_A/Q ($V_A/Q > 0$) as the main causes of reduced pulmonary oxygen transfer.[20] Diffusion impairment is rarely implicated.[21] Shunt predominates in ARDS, lobar pneumonia and after cardiopulmonary bypass, whereas V/Q mismatch causing low V_A/Q is prominent in chronic obstructive pulmonary disease, often with minimal shunt.[22,23]

Current clinical indices of pulmonary oxygen transfer cannot make these distinctions. They consist of two main groups, 'tension-based' and 'content-based'.

Tension-Based Indices

A-a Gradient

The A-a gradient is calculated as $PAO_2 - PaO_2$, where PAO_2 is the 'ideal' alveolar PO_2 (Eqs. 38.2 and 38.3). Hypoxaemia, which is $PaO_2 < 60$ mm Hg, can be classified as either 'normal' or 'raised' A-a gradient in type:

1. **Normal A-a gradient** :
    - Alveolar hypoventilation (elevated $PACO_2$).
    - Low PiO_2 ($FiO_2 < 0.21$, or barometric pressure <760 mm Hg).
2. **Raised A-a gradient** :
    - Diffusion defect (rare).
    - V/Q mismatch.
    - Right to left shunt (intrapulmonary, intracardiac).
    - Increased oxygen extraction ($CaO_2 - CvO_2$).

The A-a gradient is a component of the APACHE II, III and IV scoring systems.[24,25] Drawbacks include:

- Varies non-linearly with FiO_2.[26,27]
- Dependence on FiO_2 and age. Normal values at sea level:
  - 7 mm Hg (young adults) and 14 mm Hg (elderly) breathing air.
  - 31 mm Hg and 56 mm Hg respectively breathing 100% O_2.

PaO_2/FiO_2 Ratio

The PaO_2/FiO_2 ratio contributes to ARDS diagnosis,[28] stratifying severity as mild (<300 ≥ 200), moderate (<200 ≥ 100), or severe (<100). It is an input variable in SAPS 2 and 3,[29] SOFA,[30] APACHE IV,[25] and lung injury scoring systems.[31] Normal sea-level value is ≥500 mm Hg.

Simplicity is the main advantage. There are several disadvantages:

- Inability to distinguish hypoventilation from other causes of hypoxaemia.
- Interpretation dependent on barometric pressure. A PaO_2/FiO_2 ratio of 380 mm Hg is low at sea level but unremarkable at 1600 metres elevation.
- FiO_2 dependence.[26,27]

PaO_2/FiO_2 calculated on standardised FiO_2 and PEEP settings 24 hours post-intervention can reset ARDS classifications and improve hospital mortality prediction.[32]

Content-Based

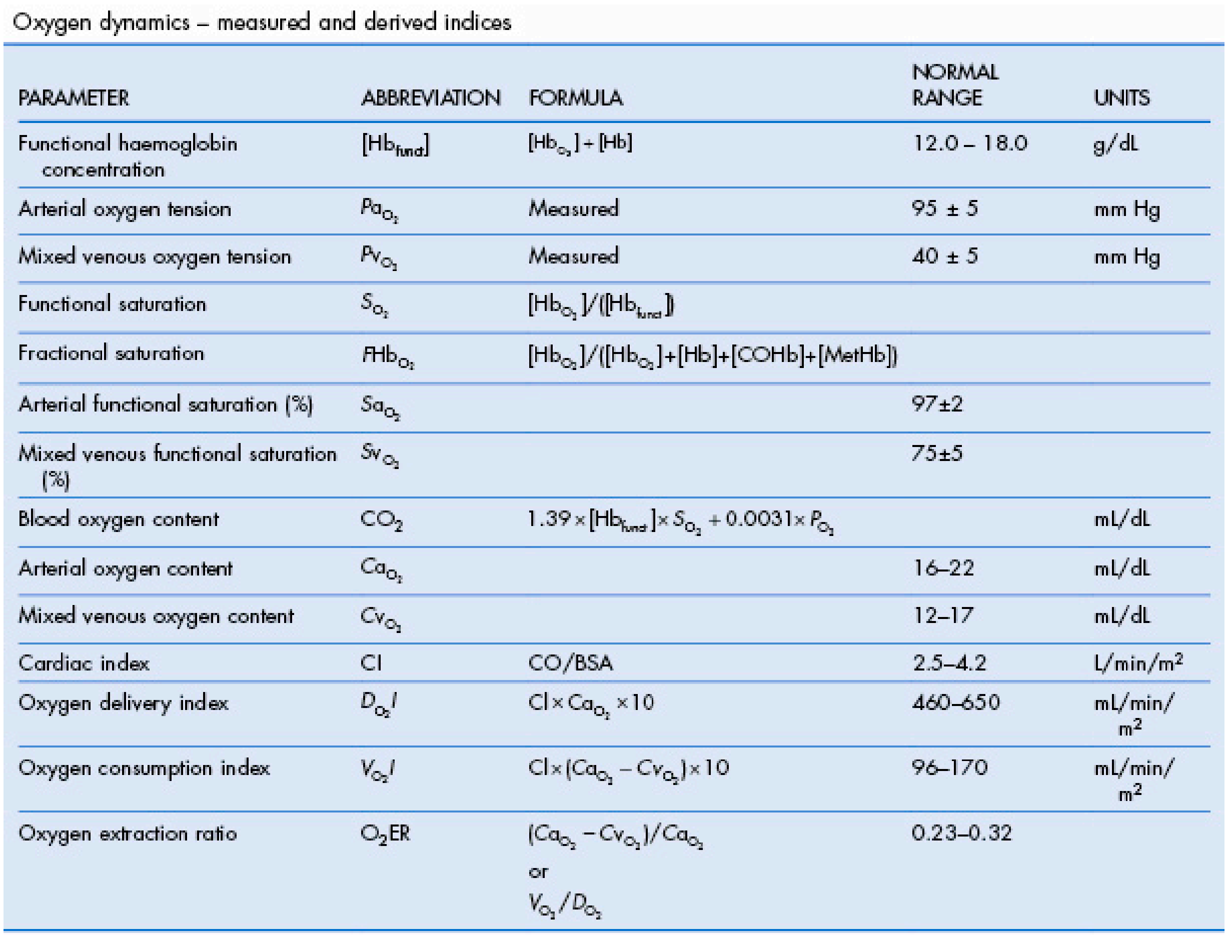
Venous Admixture (Q_s/Q_t)

Venous admixture is the proportion of mixed venous blood calculated to flow through the ‘shunt’ ($V_i / Q = 0$) compartment of the three-compartment model which on re-joining ‘ideal’ end-capillary blood would reproduce the measured PaO_2. It is determined as:

$$\frac{\dot{Q}_S}{\dot{Q}_T} = \frac{Cc'O_2 - CaO_2}{Cc'O_2 - C\overline{v}O_2} \qquad \textbf{(38.4)}$$

$Cc'O_2$, CaO_2 and CvO_2 are oxygen contents of ‘ideal’ end-capillary, arterial and mixed venous blood respectively. CaO_2 is calculated from arterial blood gas analysis and CO-oximetry. CvO_2 is determined similarly from sampled mixed venous blood or else computed from arterial values after calculating oxygen extraction using measurements of oxygen consumption (VO_2) and cardiac output (Table 38.1). $Cc'O_2$ is calculated from PAO_2 (Eqs. 38.2 and 38.3) and ScO_2, which is computed from the HbO_2 dissociation curve (assuming $Pc'O_2 = PAO_2$).

Table 38.1



Oxygen dynamics – measured and derived indices

PARAMETER	ABBREVIATION	FORMULA	NORMAL RANGE	UNITS
Functional haemoglobin concentration	$[Hb_{funct}]$	$[Hb_{O_2}]+[Hb]$	12.0 – 18.0	g/dL
Arterial oxygen tension	Pa_{O_2}	Measured	95 ± 5	mm Hg
Mixed venous oxygen tension	Pv_{O_2}	Measured	40 ± 5	mm Hg
Functional saturation	S_{O_2}	$[Hb_{O_2}]/([Hb_{funct}])$		
Fractional saturation	FHb_{O_2}	$[Hb_{O_2}]/([Hb_{O_2}]+[Hb]+[COHb]+[MetHb])$		
Arterial functional saturation (%)	Sa_{O_2}		97±2	
Mixed venous functional saturation (%)	Sv_{O_2}		75±5	
Blood oxygen content	CO_2	$1.39 \times [Hb_{funct}] \times S_{O_2} + 0.0031 \times P_{O_2}$		mL/dL
Arterial oxygen content	Ca_{O_2}		16–22	mL/dL
Mixed venous oxygen content	Cv_{O_2}		12–17	mL/dL
Cardiac index	CI	CO/BSA	2.5–4.2	L/min/m^2
Oxygen delivery index	$D_{O_2}I$	$CI \times Ca_{O_2} \times 10$	460–650	mL/min/m^2
Oxygen consumption index	$V_{O_2}I$	$CI \times (Ca_{O_2} - Cv_{O_2}) \times 10$	96–170	mL/min/m^2
Oxygen extraction ratio	O_2ER	$(Ca_{O_2} - Cv_{O_2})/Ca_{O_2}$ or V_{O_2}/D_{O_2}	0.23–0.32	

BSA, Body surface area; *COHb,* carboxyhaemoglobin; *Hb,* reduced haemoglobin; HbO_2, oxyhaemoglobin; *MetHb,* methaemoglobin.

Advantages:

- Unaffected by barometric pressure
- Unaffected by hypoventilation
- Independent of FiO_2 provided intrapulmonary shunt is the dominant pathology. [26, 33]

Disadvantages:

- Requires either a pulmonary artery catheter or indirect calorimetry plus cardiac output measurement.[34]
- Groups low V/Q and shunt together as ‘venous admixture’.
- FiO_2 dependence in V/Q heterogeneity, for example in chronic obstructive pulmonary disease.

Although venous admixture determined at $FiO_2 = 1$ estimates ‘true’ right to left shunt, 100% oxygen exposure increases intrapulmonary shunt by absorption atelectasis and inhibition of hypoxic pulmonary vasoconstriction.[14], [35], [36]

Estimated Venous Admixture

Assigning a fixed oxygen extraction ($CaO_2 - CvO_2$) allows a venous admixture ‘estimation’. However, the wide extraction range (1.3–7.4 mL/dL) means substantial error is possible in either direction.[33]

Distinguishing Shunt from Low V/Q

This influences management in conditions such as COVID-19 pneumonia.[37] Methodologies considerably less challenging than MIGET can separate these two mechanisms. They include:

1. **The Automatic Lung Parameter Estimator (ALPE)**

Described as a ‘simple bedside alternative to MIGET’,[38] ALPE has produced research data on ARDS,[3] and contributes to a commercial decision support package. From bedside data, ALPE reports shunt as percentage of cardiac output while quantifying ‘low V/Q’ and ‘high V/Q’ mismatch as partial pressure gradients across notional ‘partitions’ between pulmonary capillary blood and alveolar gas.

ALPE evaluations require:

- Arterial blood gas analysis.

- Measurements of cardiac output, indirect calorimetry and end-tidal O_2 and CO_2 fractions.
- Arterial oxygen saturations by pulse oximetry (SpO_2) at up to five FiO_2 settings.[3]

2. **Machine Learning**

In an in-silico simulation, a trained machine learning application partitioned venous admixture into its shunt and low V/Q components using data from blood gas analysis, indirect calorimetry and cardiac output measurements.[34] After adding volumetric capnography and applying a 'deep learning' approach, a single set of measurements at any operating FiO_2 was sufficient.[39]

Arterial Blood

Oxygenation indices are PaO_2 and SaO_2, linked by the HbO_2 dissociation curve.

Hypoxaemia is defined as $PaO_2 < 60$ mm Hg or $SaO_2 < 0.9$, values near the descending portion of the HbO_2 dissociation curve.

Blood Gas Analysis and CO-Oximetry

Blood is collected in a purpose-designed syringe containing 20–50 U/mL lyophilised heparin. A Clark electrode measures PO_2 on polarographic principles. SO_2 is determined by CO-oximetry which computes the concentrations of haemoglobin species (HbO_2, Hb, COHb, MetHb and FHb) from light absorbances of haemolysed blood at several wavelengths.

SO_2 is 'functional' saturation, determined solely from concentrations of HbO_2 and Hb (Table 38.1). It is the fraction of *effective* Hb that is oxygenated, whereas the fractional saturation (FO_2Hb) uses the *total* Hb. Interferences arise from substances with competing absorbance spectra, such as bilirubin, HbF, lipid emulsions and intravenous dyes. Increasing the number of wavelengths, for example from 7 to 128, can reduce or eliminate interferences.

Errors

Pre-analytic and analytic errors in PO_2 measurement are set out in Table 38.2 .

Table 38.2

Temperature Correction

Analysers operate at 37°C. Temperature-corrected values can be calculated, but many clinicians prefer uncorrected data interpreted using 37°C reference ranges.

Continuous Arterial Blood Gas Monitoring

1. **In-line measurement**

Calibrated fibre-optic optodes in the arterial stream provide continuous measurements of pH, $PaCO_2$ and PaO_2 . [40] However, after problems with artefact, bias and imprecision, [41] the only continuous in-line device in clinical use at the time of writing monitors pumped blood during cardiopulmonary bypass. [42]

2. **In-line sampling with ex-vivo measurement**

Samples drawn into an external cassette are analysed and then returned, with results available in two minutes. This method has reduced red cell transfusion requirements in pre-term neonates. [43]

3. **Transcutaneous measurement**

Transcutaneous monitors can be employed in sleep laboratories, during non-invasive ventilation,[44] and to prevent neonatal hyperoxia.[45] PO_2 measurement is by Clark electrode and PCO_2 by a modified pH-sensitive glass electrode.

Cutaneous O_2 diffusion resistance exceeds CO_2 diffusion resistance. Measurements via the thin skin of neonates and young children best approximate arterial values. For PO_2 the skin must be warmed to 42°C–44°C, whereas PCO_2 can be tracked at lower skin temperatures.[46]

In adults, the technique is primarily for trend monitoring and is not recommended during haemodynamic instability. Frequent site changes prevent burns. In time ‘fluorescence quenching’ style optodes may supersede the Clark electrodes. Recalibration requirements are less frequent, and O_2 is not consumed during measurement.[46]

Pulse Oximetry

Dual wavelength pulse oximetry[47] determines SpO_2 in capillary beds (e.g. digits, ear lobes) from light absorbance at wavelengths 660 nm (red) and 940 nm (infrared). The selected wavelengths exploit differences in Hb and HbO_2 absorption spectra. Paired light-emitting diodes cycle on and off at multiples of mains frequency. A photodiode detects transmitted light and corrects for ambient light. Subtraction of background signals (capillary and venous blood, tissue) isolates the pulsatile arterial component by a technique known as ‘photoplethysmography’.[48]

Absorbance (A) for both wavelengths is determined as:

$$A = \log_{10}(I_0/I)$$

where I_0 is incident light intensity and I is emergent light intensity. The pulsatile (AC) and background (DC) absorbances derive the ratio (R):

$$R = (AC_{660}/DC_{660})/(AC_{940}/DC_{940})$$

SpO_2 , usually displayed as a percentage is computed from ‘look-up’ *R* versus SaO_2 tables based on data from volunteers breathing hypoxic gas mixtures.

Speed of Response

SpO_2 is averaged over 3–6 seconds and updated every 0.5–1 second. Forehead sensors measuring by reflectance [48] respond to sudden FiO_2 reductions in 10–15 seconds. With peripheral vasoconstriction finger probe delay can exceed one minute.

Accuracy

In the 90%–97% saturation range, SpO_2 has a mean absolute bias of <1%, and a precision (SD of bias) of <3%. Maintaining $SpO_2 > 94\%$ has been recommended to ensure $SaO_2 > 90\%$. [49], [50] In newborns with their HbF preponderance, switching to the foetal measurement matrix averts a further 4% error. [51] Because low SpO_2 readouts are extrapolated from volunteer calibrations at higher saturations, negative bias and imprecision increase progressively at $SaO_2 < 80\%$

Error

Causes are listed in Table 38.3 . A falsely high SpO_2 is of greatest concern. When ‘hidden hypoxaemia’ is defined as a true SaO_2 less than 88% with a SpO_2 ranging between 92% and 96%, white patients had a frequency of 3.6%, about three times lower than the frequency in black patients (11.7%). [52] Using an alternative definition, ‘hidden hypoxaemia’ has been shown to occur in a wide range of races with greater frequency related to skin pigmentation.[53] Associations with mortality and organ dysfunction reinforce the importance of this phenomenon. Heightened clinical awareness and calibration of pulse oximetry with arterial saturation using blood gas and CO-oximetry should be considered. Further information is awaited from ongoing clinical trials. Unlike CO-oximetry, there is no interference from bilirubin and lipid emulsions.

Table 38.3

Causes of error in SpO_2 readings

FACTOR	COMMENT
COHb	Measured as HbO_2. SpO_2 may be falsely high
MetHb	Absorbs both wavelengths. See *Dyshaemoglobins and pulse oximetry*
Low saturations	Progressive inaccuracy below 70%–80%, usually falsely low SpO_2
Prominent venous signal	Dependent limb, tricuspid regurgitation (venous pulsations) – falsely low SpO_2
Non-pulsatile flow	Cardiopulmonary bypass – poor signal
Vasoconstriction, limb ischaemia, shock states	Low pulsatile signal
Motion artefact	Tremor, voluntary movement – falsely low SpO_2
Ambient light	Strong sunlight, fluorescent and xenon lamps, flickering light – falsely low SpO_2
Anaemia	No effect
Dyes	Methylene blue, indocyanine green, indigo carmine – falsely low SpO_2
Dark skin pigmentation	Variable precision and bias, increasing the risk of hidden hypoxaemia. May require separate calibration. See also ‘Signal Extraction’

FACTOR	COMMENT
Nail polish	Especially blue. Falsely low SpO_2. Acrylic nails do not interfere
Optical shunting	Due to inadequate probe contact – falsely low SpO_2
Radiofrequency interference	Reported with MRI scanners – falsely high SpO_2

MRI, Magnetic resonance imaging.

Dyshaemoglobins and Dual-Wavelength Pulse Oximetry

With normal dyshaemoglobin concentrations error is trivial. However, because oximeters cannot distinguish COHb from HbO_2, SpO_2 can provide false reassurance when [COHb] is elevated, for example after inhalational burn injuries. High [MetHb] causes SpO_2 under-estimation of SaO_2 at normal saturations and over-estimation at very low oxygen tensions. At [MetHb] $\geq$ 35% the R value is unity, which translates to $SpO_2 = 85\%$.

Innovations and Variants

1. **Reflectance oximetry**
    - Forehead reflectance oximetry shows evidence of superiority over digital absorbance oximetry in low-flow states. [54]
    - Other potential reflectance sites include the oesophagus, pharynx, trachea and even the finger surface. [47]
2. **Signal extraction**

    By isolating saturation ‘components’ in the optical pathway, signal extraction:

  - facilitates uninterrupted SpO_2 monitoring during motion and in episodes of poor tissue perfusion. [48]
  - maintains similar accuracy in light and dark-skinned patients during hypoxaemia. [55]

3. **Oximetric respiratory rate monitoring** [56]
   - When oxygen is administered to patients monitored by standard pulse oximetry, hypoventilation can escape detection. [57]
   - Algorithms can detect respiration-induced oximetric signal changes.
   - May supersede current methods such as chest bands or nasal end-tidal CO_2. [56]
4. **Multi-wavelength pulse oximetry**
   (a) **Peripheral perfusion index (PPI)**
     - A third wavelength of 800 nM is added for which Hb and HbO have similar absorbances.
     - PPI is the ratio between the arterial pulsatile component and the background absorbance. [58]
     - Low PPI values can provide an early signal in hypovolaemia [59], [60] and flag illness severity in neonates. [61]
     - Higher PPI values are poorly predictive of SpO_2/SaO_2 correlation. [62]

   (b) **Oxygen reserve index**

Signal separation of venous and arterial saturations allows limited quantification of the ‘oxygen reserve’ when $SpO_2 \approx 100\%$ and $PaO_2 = 100–200$ mm Hg. [63] Potential applications include:

- Assessing the adequacy of pre-oxygenation.
- Assessing responses to recruitment manoeuvres. [64]
- Prevention of hyperoxia.

   (c) **Pulse CO-oximetry** [63]

- Non-invasive tracking of total haemoglobin (SpHb), carboxyhaemoglobin (SpCO) and methaemoglobin (SpMet) concentrations.
- Includes low perfusion states.
- Mainly for trend monitoring. [65]

Importance of Pulse Oximetry

- Generates rapid real-time information without calibration.
- Useful screening tool.
- Detects unsuspected hypoxaemia during patient transport. [66]
- Mandatory in high acuity areas such as operating rooms, recovery rooms, intensive care units and emergency departments.

Problems with pulse oximetry:

- Insensitive to higher PaO_2 changes (>70–100 mm Hg).
- Common source of false alarms.
- Potentially affected by patient skin tone.

Haemoglobin-Oxygen Affinity

Haemoglobin-oxygen affinity is the relationship between the oxygen tension of blood and its oxygen content, described by the sigmoid-shaped HbO_2 dissociation curve. The P_{50} is the oxygen tension at $SO_2 = 0.5$. The normal value in adult humans is 26.7 mm Hg.

Factors which decrease haemoglobin-oxygen affinity increase the P_{50}. They include:

- Acidaemia (Bohr effect).
- Hypercarbia.
- Increased erythrocytic 2,3-DPG.
- Fever.

P_{50} is decreased (increased affinity) by:

- Alkalaemia.
- Hypocarbia.
- Low 2,3-DPG concentrations.
- Hypothermia.
- COHb, MetHb and FHb.

Accurate P_{50} values can be calculated from a single measurement of SO_2 and venous or arterial blood gases up to $SO_2 = 0.97$. Although in theory the P_{50} can be manipulated to improve tissue oxygenation, [67] any clinical impact is yet to be established.

Titrating Oxygen Therapy in Critical Illness

Avoidance of hypoxaemia must be counterbalanced against risks of hyperoxia. The optimal oxygenation range is unclear.

- A 2016 single centre trial ($n = 480$) supported the hypothesis that FiO_2 titrated to $PaO_2 = 70–100$ mm Hg versus ≤150 mm Hg or $SpO_2 = 94\%–98\%$ versus 97%–100% produces a lower ICU mortality and fewer episodes of shock and liver failure. [68]
- In a subsequent 4-centre study in 2021, ‘low-normal’ versus ‘high-normal’ PaO_2 targets produced no statistically significant differences in organ dysfunction in patients with 2 or more SIRS criteria. [69]
- Two randomised controlled studies in pre-term infants targeting $SpO_2 = 85\%–89\%$ versus $SpO_2 = 91\%–95\%$ to prevent retinopathy of prematurity demonstrated higher mortality in the permissive hypoxaemia groups. [70, 71]

Monitoring Oxygen Dynamics

Oxygen dynamics describes variables such as the global delivery (DO_2) and consumption (VO_2) of oxygen, and their indices. Some common indices are set out in Table 38.1 .

DO_2/VO_2 Relationships

In 1973 a reported association between hyperdynamic DO_2 patterns and survival after high-risk non-cardiac surgery [72] led to the popular hypothesis that an induced hyperdynamic state could mitigate an acquired oxygen debt. [73] Common goals were CI > 4.5 L/min/m^2, $DO_2I > 600$ mL/min/m^2, $VO_2I > 170$ mL/min/m^2. However:

- VO_2I targets were difficult to achieve.
- Outcomes were not improved in multi-centre studies. [74, 75]
- Positive outcomes continued to be evident in patients spontaneously achieving hyperdynamic patterns. [76]
- DO_2I as sole target was linked to an improved composite morbidity/mortality endpoint on Bayesian reanalysis of one multi-centre dataset. [77]

From a 2012 Cochrane report: ‘It remains uncertain whether increasing blood flow using fluids, with or without inotropes or vasoactive drugs, reduces mortality in adults undergoing surgery’. [78] A subsequent meta-analysis recommended further well-designed, adequately powered trials on peri-operative goal-directed therapy. [79] A multi-centre study enrolling over 2500 patients is underway at the time of writing. [80]

Estimating DO_2I

A PA catheter is not essential (Table 38.1). Isolated measurements are difficult to interpret due to varying oxygen demand.

Estimating VO_2I

Two methods are the reverse Fick method (Table 38.1) and indirect calorimetry.

Reverse Fick Method

Using a PA catheter changes in temperature in the pulmonary artery following a right atrial injection (thermodilution) are used to estimate cardiac output. Changes <20% cannot be detected reliably. In lung inflammation up to 20% of VO_2I measured by Reverse Fick arises directly from the lungs.

Indirect Calorimetry

Indirect calorimetry has better accuracy. VO_2I is determined from the volumes and oxygen concentrations of inspired and expired gas. Errors are <5% up to $FiO_2 = 0.8$. Higher FiO_2 settings increase error. VO_2I by indirect calorimetry has predicted weaning success,[81] and provides input data for multi-compartment gas exchange monitoring.[34, 38, 39]

Mixed Venous Blood

Mixed venous blood can be sampled by gentle aspiration of the distal port of an unwedged PA catheter. The distal site ensures adequate admixture of blood from the superior and inferior venae cavae and the coronary sinus.

1. **Mixed venous PO_2 (PvO_2)**

A $PvO_2 < 26$ mm Hg is suggestive of cellular hypoxia.[82] A normal or high PvO_2 does not exclude regional cytopathic dysoxia[83] or hypoxia due to tissue shunting.[84]

2. **Mixed venous oxygen saturation (SvO_2)**

SvO_2 is measured either intermittently by mixed venous sampling and CO-oximetry or continuously by a PA catheter incorporating fibre-optic reflectance oximetry. Measurements have several applications:

- To calculate CvO_2 (Table 38.1). CvO_2 can then be used to determine Q_s/Q_t, VO_2I (Reverse Fick), the oxygen extraction ratio (Table 38.1) and cardiac output (Fick).
- As an index of tissue oxygenation:
  - SvO_2 values between 70% and 80% imply but do not guarantee balanced global oxygen supply and demand.
  - Lactic acidosis appears between 30% and 50%,[85] although values <50% seem well tolerated in chronic heart failure.
  - Values >80% occur in high-flow states such as sepsis, hyperthyroidism and severe liver disease.

Like PvO_2, SvO_2 is insensitive to cytopathic dysoxia[83] and tissue shunting. $SvO_2 \geq 70\%$ as a therapeutic target failed to improve survival.[86]

Central Venous Saturation ($ScvO_2$)

$ScvO_2$ can be measured either continuously using a central venous catheter modified for reflectance oximetry, or by intermittent sampling and CO-oximetry. In health $ScvO_2 < SvO_2$ by 2%–3%. In shock, the difference can be reversed. Trends usually run in parallel.

Enthusiasm lessened for this monitoring approach after three randomised trials with $ScvO_2 > 70\%$ as part of early goal-directed therapy protocols failed to produce a mortality benefit.[87]

Mixed Venous-Arterial PCO_2 Gradient (Pv-aCO_2), Central Venous-Arterial PCO_2 Gradient (ΔPCO_2) and Derived Variables

$Pv\text{-}aCO_2$ (normally about 6 mm Hg) increases during low-output states as a reflection of reduced CO_2 clearance, further modified by the Haldane effect, metabolic acidosis and haematocrit.[88] Similar comments apply to ΔPCO_2.

High or sudden increases in the respiratory quotient (VCO_2/VO_2) or in $Pv\text{-}aCO_2$ are more specific markers of DO_2/VO_2 dependence. Corresponding values calculated from central venous samples have also shown promise in early septic shock.[89] In ventilated septic patients without DO_2/VO_2 dependence, ΔPCO_2 may predict fluid responsiveness.[90]

Regional Indices

Direct Tissue PO_2 Measurement

In animals, measurements have been recorded in the brain, subcutaneous tissue, muscle, and renal beds using Clarke electrodes under various perfusion insults. Tensions range from <10 mm Hg in the renal medulla to >70 mm Hg in subcutaneous tissue. Tissue beds differ in responses to hypoxic or hypotensive insults,[91] and identification of dysoxic thresholds is difficult. This approach is currently impractical in patients, although MRI has potential.[92], [93]

Near Infrared Spectroscopy (NIRS)[94]

NIRS quantifies differential HbO_2 and Hb absorbances in vessels with diameter <1 mm (arterioles, venules and capillaries) <2.4 mm in depth subjected to the light of wavelengths 700–1000 nm. The thenar eminence is preferred for tissue measurements due to its low subcutaneous thickness and amenability to proximal vascular occlusion. Cerebral NIRS is also available.

Vascular Occlusion Test

The NIRS vascular occlusion test is designed to detect covert microcirculatory dysfunction in skeletal muscle. The sphygmomanometer cuff is inflated >30 mm Hg above systolic pressure either for 3 minutes or until tissue haemoglobin saturation (StO_2)=40%, then released. Indices which vary with shock and sepsis include:

- The desaturation slope (DeO_2).
- The resaturation slope (ReO_2) on cuff release.
- Markers of reactive hyperaemia post release.

The test may add little to tracking plasma lactate concentrations, [95] although trials targeting specific interventions in peri-operative care are recommended. [96, 97]

Carbon Dioxide

CO_2 is generated aerobically within mitochondria ($VCO_2 \approx 200$ mL/min) and descends along partial pressure gradients, ultimately exiting to the atmosphere (PCO_2 =0.4 mm Hg). Typical cell-to-atmosphere driving pressures are low (≤50 mm Hg) due to:

- Densely invested tissue micro-circulations.
- Widespread carbonic anhydrase distribution, massively accelerating dissolved CO_2/bicarbonate transitions.
- Haldane and Hamburger effects enhancing venous CO_2 transport.
- An extensive, thin, continually refreshed air-blood barrier.

$PaCO_2$

- Usually measured by blood gas analysis using a modified pH (Severinghaus) electrode.
- Transcutaneous methods are less accurate (see ‘Transcutaneous measurement’ above).

- Alveolar ventilation and CO_2 production (VCO_2) are major factors determining $PaCO_2$:

$$PaCO_2\,(\text{mm Hg}) = [VCO_2\,(\text{mL/min STPD}) \times 0.863/V_{\text{alv}}\,(\text{L/min BTPS})]$$

where V_{alv} is minute ventilation (V_E) − dead space ventilation (V_D).

Dead Space [98]

Respiratory dead space (V_D) is 'wasted' ventilation not participating in gas exchange. In intubated patients, V_D has three components:

- 'Equipment' or 'instrumental' V_D: Y-piece to the delivery end of the endotracheal tube.
- Anatomical V_D (V_{Danat}): Without intubation, V_{Danat} normally = 30% of tidal volume (V_T). In intubated ventilated patients, equipment V_D reduces V_{Danat} by an amount approximating its own V_D, with minimal overall effect.
- Alveolar V_D (V_{Dalv}): Ventilated non-perfused lung units. Normally V_{Dalv} is negligible (see later).

V_{Danat} was first measured functionally by Fowler's method, a geometric analysis of exhaled N_2 concentrations after 100% O_2 inspiration. On similar principles, volumetric capnography can provide V_{Danat} estimates from single-breath CO_2 waveforms. [99]

Physiological Dead Space

Physiological dead space (V_{Dphys}) is defined as:

$$\mathrm{V_{Dphys} = V_{Danat} + V_{Dalv}}$$

This definition most correctly applies to Christian Bohr's original calculation (V_{DBohr}):

$$\mathrm{V_{DBohr}/VT = (P_ACO_2 - P_ECO_2)/P_ACO_2}$$

($\mathrm{P_A CO_2}$ is mean alveolar $\mathrm{PCO_2}$ and $\mathrm{P_E CO_2}$ is mixed expired $\mathrm{PCO_2}$)

V_{DBohr} versus V_{DEnghoff}

Because V_{DBohr} calculations were susceptible to inconsistent $\mathrm{P_A CO_2}$ determinations from sampled expired gas, the Enghoff modification (V_{DEnghoff}) substituting $\mathrm{PaCO_2}$ for $\mathrm{P_A CO_2}$ became the accepted norm. However, V_{DEnghoff} is also influenced by Shunt and V/Q heterogeneity, [98] making it more of an 'overall' index of gas exchange. This could explain why V_{DEnghoff} outperforms other common prognostic factors in ARDS. [98], [100], [101] Importantly, with the advent of volumetric capnography and single waveform analysis (see below), consistent bedside V_{DBohr} calculations are now feasible. [102]

In health, V_{Dalv} is minimal whether calculated as ($V_{\mathrm{DBohr}} - V_{\mathrm{Danat}}$) or ($V_{\mathrm{DEnghoff}} - V_{\mathrm{Danat}}$). Positive-pressure ventilation increases V_{Danat} by airway distension. V_{Dalv} calculated as ($V_{\mathrm{DEnghoff}} - V_{\mathrm{Danat}}$) also increases due to increased V/Q heterogeneity, but usually remains close to zero calculated as 'true' alveolar dead space ($V_{\mathrm{DBohr}} - V_{\mathrm{Danat}}$).

Capnography

Capnography measures and displays exhaled CO_2 (as % or as PCO_2) throughout the respiratory cycle. Sampling in intubated patients is normally done by mainstream sensors as secretions tend to block side-stream systems, which are largely reserved for non-intubated patients.

Infrared spectroscopy converts the absorbed energy fraction to $\%CO_2$ exhaled. On initial expiration, the capnograph reads 0%. CO_2 appears in the second half of V_{Danat} exhalation, rising to a plateau before returning to 0% with the next inspiration. With significant respiratory disease, a plateau may never be achieved.

Confirmation of exhaled CO_2 post-intubation is recommended even when the tube is seen to pass through the vocal cords.[103] Simple colorimetric devices may be used. However, expired CO_2 detection is itself not infallible.[103] False positives can arise from ingestion of carbonated liquids, and false negatives from extremely low pulmonary blood flow or other causes of a very large $V_{DEnghoff}$ such as pulmonary embolus or severe asthma. Capnography is also recommended during transport,[104] in all patients receiving intubated ventilator support,[105] and should be available for every anaesthetised patient.[106]

Sidestream capnography should be considered during conscious sedation, as this is associated with fewer hypoxaemic episodes, and in morbidly obese patients or those receiving significant parenteral opiates.[107] Routine supplemental oxygen reduces the sensitivity of standard pulse oximetry to hypoventilation.

End-Tidal PCO_2 ($P_{E'}CO_2$)

$P_{E'}CO_2$ is the value at end expiration, normally slightly $< PaCO_2$. The $PaCO_2 - P_{E'}CO_2$ gradient is increased by factors which increase $V_{DEnghoff}$, such as low cardiac output, pulmonary embolism, and elevated alveolar pressure. Consequently, $P_{E'}CO_2$ may not directly reflect $PaCO_2$ in critical illness, although, in a stable patient, the gradient is sufficiently constant to guide $\dot{V}_E$ during transport.[108]

Sudden shifts in $P_{E'}CO_2$ may provide an early alert. $P_{E'}CO_2$ directly correlates with cardiac output, and $P_{E'}CO_2$ monitoring has been used to assess the adequacy of cardiopulmonary resuscitation and its prognosis. [109] The $P_{E'}CO_2/PaCO_2$ ratio has shown promise in ARDS severity stratification. [110]

Volumetric Capnography [102]

In conventional ‘time-based’ capnography expired CO_2 is plotted against time. With volumetric capnography, expired V_T forms the X axis, computed as ‘flow × time’ via a pneumotachograph in the mainstream adaptor. In addition to $P_{E'}CO_2$, the method allows breath-to-breath V_{DBohr} and V_TCO_2 (and thus VCO_2) measurements by analysis of single breath waveforms, which can be distorted by tachypnea, bronchospasm, bronchial intubation, partial airway obstruction, and ventilator ‘malfunctioning’. [111]

Regional PCO_2 and the CO_2 Gap [112, 113]

Regional PCO_2 reflects the balance between arterial blood CO_2 content, tissue blood flow and tissue CO_2 production. The CO_2 gap is regional $PCO_2 - PaCO_2$. As tissue blood flow falls, reduced CO_2 clearance increases the CO_2 gap. When aerobic CO_2 production ceases, progressive regional metabolic acidosis generates further CO_2 by ‘proton titration’ of tissue and capillary HCO_3^-. A rising CO_2 gap signals falling tissue blood flow, but cannot pinpoint the onset of anaerobic metabolism. [114] Sublingual and ear lobe CO_2 gaps have been evaluated. [115, 116] It is unclear whether these techniques can guide therapy.

Gastric Tonometry

Gastric tonometry, the best-known CO_2 gap application, evolved from an earlier version which indirectly ‘measured’ gastric intramucosal pH (pHi);

however, the technique has lost impetus.[117] The concept was that splanchnic hypoperfusion, an early feature of circulatory shock, may persist as ‘covert shock’, detectable as an increased gastric CO_2 gap. The gastric CO_2 gap (normally 8–10 mm Hg) was considered an independent prognostic factor in critical illness.[118] Simultaneous $P_{E'}CO_2$ measurement allowed monitoring of the gastric to $P_{E'}CO_2$ gap, a parameter linked to outcome in high-risk surgery.[119]

Barriers to adoption included:

- The need for a nasogastric tube.
- Signal degradation by luminal contents, including feeds and blood.
- Stopping feeds two hours prior to measurements, jeopardising nutritional support.
- Gastric acidity suppression to prevent CO_2 back-generation by titration of duodenal bicarbonate.
- Lack of a clear action threshold.
- Limited evidence that tonometry-guided therapy improved outcomes, although a 2015 meta-analysis which included older pHi-based trials did report a composite mortality reduction.[120]

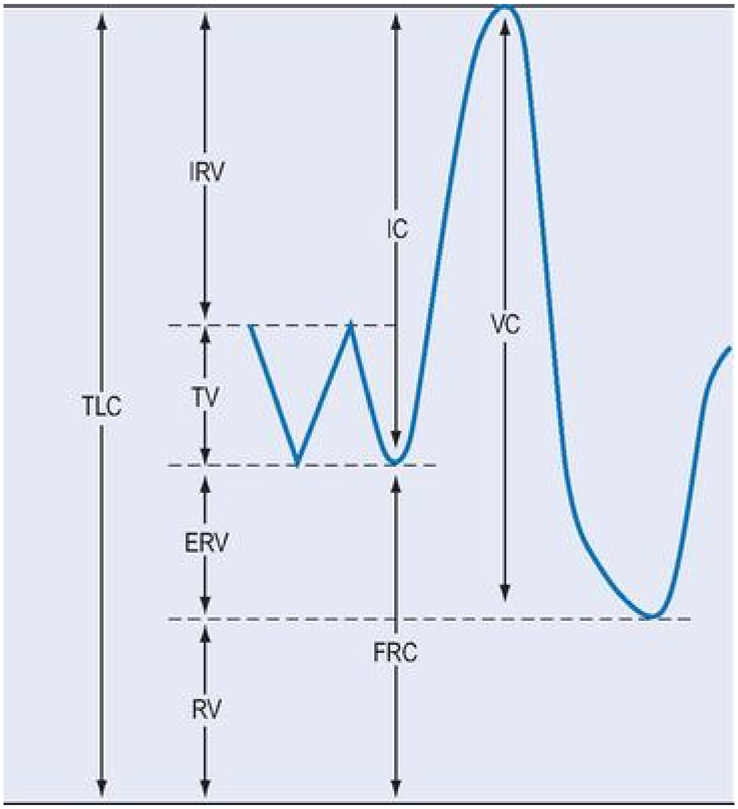
Gas Transfer (Diffusing Capacity)

This is a test of the transfer of a gas, typically carbon monoxide (CO), across the alveolocapillary barrier. The transfer factor is calculated as:

volume CO uptake/($PA_{CO} - Pc_{CO}$) and, as CO is so completely taken up by Hb, Pc_{CO} is taken as zero. This test is usually performed as an outpatient, is not usually measured in ICU, and diffusion abnormality is rarely a cause of hypoxaemia. The transfer factor is often corrected for lung volume since diseases such as emphysema and pulmonary fibrosis may affect both lung volume and diffusion. In chronic heart failure, diffusing capacity is reduced and correlates with exercise performance and chronic heart failure (CHF) severity and prognosis due to a reduction in the volume of alveolar tissue and amount of blood participating in gas exchange.[121]

Lung Volume and Capacities

The tidal volume (V_T) is the volume of gas inspired and expired with each breath, and the volume at end expiration and zero positive end-expiratory pressure (PEEP) is the functional residual capacity (FRC); the end-expiratory lung volume (EELV) is the volume at end expiration at a specified PEEP so that at PEEP 0 cm H_2O FRC is equal to EELV (Fig. 38.1). The residual volume (RV) is the FRC minus the expiratory reserve volume (ERV). If a maximum inspiratory effort is made from FRC, this is termed a vital capacity (VC) manoeuvre when the total lung capacity (TLC) is reached. Clinically, the most important of these are the FRC, EELV, V_T and VC and the latter two are easily measured using a spirometer or integrated from the flow.



The graph plots lung volume on the vertical axis with several labelled levels. From top to bottom, the labels read total lung capacity, inspiratory reserve volume, inspiratory capacity, vital capacity, tidal volume, expiratory reserve volume, functional residual capacity, and residual volume. A wave pattern spans the width of the graph, which represents changes in lung volume over time. The wave starts at functional residual capacity, rises to a peak near inspiratory capacity, dips back to functional residual capacity, drops further to residual volume, and then rises again to functional residual capacity.

FIG. 38.1 Lung volumes and capacities. *ERV* , Expiratory reserve volume; *FRC* , functional residual capacity; *IC* , inspiratory capacity;

IRV , inspiratory reserve volume; *RV* , residual volume; *TLC* , total lung capacity; *TV* , tidal volume; *VC* , vital capacity.

Tidal Volume

Minute volume is composed of f and V_T – normally ~17 breaths/min and ~400 mL, respectively, in adults. [122] Rapid shallow breathing is common in patients with respiratory distress and in those failing weaning. Although the f / V_T ratio greater than 100 was initially shown to be highly predictive of weaning failure, [123] subsequent studies have reported varying results.

Vital Capacity

At TLC, inspiratory muscle forces are counterbalanced by elastic recoil of the lung and chest wall (CW). Both these parameters and the size of the lung, which varies with body size and gender (Box 38.1), determine TLC. VC, the difference between TLC and RV, is also reduced by factors that reduce FRC (e.g. increased abdominal CW elastance and premature airway closure in chronic obstructive pulmonary disease [COPD]). The normal VC is ~70 mL/kg; although reduction to 12–15 mL/kg has been suggested as an indication for mechanical ventilation, many other factors need to be considered, including the patient's general condition, the strength of the expiratory muscles, glottic function and the response to non-invasive ventilation. Indeed, many chronically weak patients are able to manage at home with extremely low VC with the assistance of non-invasive ventilation.

Box 38.1

Factors that decrease vital capacity

Decreased muscle strength

- Myopathy
- Neuropathy

- Spinal cord injury

Increased lung elastance

- Pulmonary oedema
- Atelectasis
- Pulmonary fibrosis
- Loss of lung tissue

Increased chest wall elastance

- Pleural effusion
- Haemothorax
- Pneumothorax
- Kyphoscoliosis
- Obesity
- Ascites

Reduced functional residual capacity

- Atelectasis
- Premature airway closure (e.g. chronic obstructive pulmonary disease)

End-Expiratory Lung Volume

Direct measurement of EELV is rare in the ICU. Anatomical rather than functional estimates of EELV can be derived from CT scans, and while this remains a research standard it is not used clinically due to logistics. Techniques such as nitrogen or oxygen washout [124] are becoming available on modern ventilators but concerns regarding accuracy limit their use to changes in EELV greater than 200 mL. [125] When EELV is less than the closing volume, the lung volume at which airway closure is present during expiration, there is a marked increase in V_A / Q mismatch. Consequently, PEEP is commonly used to elevate EELV. Increases in lung volume above resting lung volume can also be directly measured from a prolonged expiration to atmospheric pressure using either a spirometer or integration of flow, [126] or by repeated EELV measurements. [127] FRC is decreased in ARDS and pulmonary oedema, in patients with abdominal distension, and following abdominal and thoracic surgery. Increased FRC places the diaphragm at a mechanical disadvantage, and is seen with severe air-flow limitation and dynamic overinflation, and when there is loss of elastic recoil (e.g. emphysema).

Electrical Impedance Tomography

Electrical impedance tomography (EIT) uses impedance variation (as gas is a poor conductor) derived from multiple CW electrodes to monitor regional tidal ventilation. This is usually performed following a recruitment manoeuvre or change in PEEP setting. [128] Care must be taken to differentiate the diaphragm from a collapsed lung, as the diaphragm moves cephalad both during expiration and at lower lung volumes. EIT can be calibrated to volume and used to examine changes in EELV but not FRC itself. PEEP may be adjusted to these changes and to indices of heterogeneity of ventilation. Automated summary analyses are being developed which may help assess variables such as the balance between non-aerated and overdistended lung. [129] Other developments include the assessment of lung perfusion and regional pulmonary function testing; however, clinical trials are needed prior with the potential to influence patient care to widespread use.

Measurement of Lung Mechanics

The forces the respiratory muscles must overcome during breathing are the elastic recoil of the lung and CW, and airway and tissue resistance. During controlled mechanical ventilation, the ventilatory pressures reflect the work done to overcome these forces; however, during partial ventilatory support, the pressure at the airway opening reflects both these forces and those generated by the respiratory muscles. Estimates of respiratory mechanics are often readily available and can assist titration of ventilatory support.

Elastic Properties of Lung and Chest Wall

The respiratory system is composed of the lung and CW, which is comprised of the rib cage and abdomen. Although it is often convenient to consider respiratory system mechanics as implying information about the lung, abnormal CW compliance can markedly influence these measurements.[130–134]

The pressure gradient across the lung (P_L) that generates gas flow is equal to the difference between the pressure at the airway opening (P_{ao}) and the mean pleural pressure (P_{pl}), which is estimated as the oesophageal pressure (P_{es}):

$$P_{\mathrm{L}} = P_{\mathrm{ao}} - P_{\mathrm{es}} \tag{38.5}$$

Although the P_{es} is not always an accurate measure of the absolute P_{pl} , the change in P_{es} reflects the change in P_{pl} . However, this requires an appropriately positioned and functioning oesophageal balloon. In spontaneously breathing subjects, a thin latex balloon sealed over a catheter is introduced into the lower third of the oesophagus and P_{es} and P_{ao} are measured simultaneously during an end-expiratory airway occlusion. A well-positioned oesophageal balloon will have a ratio of $\Delta P_{es} / \Delta P_{ao}$ of ~1.[135] This technique is reliable in supine, intubated spontaneously breathing patients[136] and in paralysed subjects, it appears that a similar pressure change, induced by manual rib cage pressure,[137] can be used to verify oesophageal balloon function.

CW mechanics are derived from P_{es} referenced to atmospheric pressure and, in ventilated relaxed subjects, RS mechanics are derived from P_{ao} referenced to atmospheric pressure. It is not surprising then that $P_{RS} = P_L$

+ P_{CW} . Finally, abdominal mechanics can be estimated as either intravesical or intragastric pressure. However, despite these provisos, useful information can be obtained from respiratory system mechanics.

Measuring the slope of the $V – P$ relationship of the lung or respiratory system allows a simple estimate of the elastic properties of the lung. Since the E_{RS} is directly related to its components ($E_{RS} = E_L + E_{CW}$), it is preferred to comply, which is inversely related: $1/C_{RS} = 1/C_L + 1/C_{CW}$. The normal E_{RS} is 10–15 cm H_2O/L and the normal C_{RS} is 60–100 mL/cm H_2O in ventilated patients.

Positive End-Expiratory Pressure-Titration Using Transpulmonary Pressure

Using a V_T of 6 m/kg pbw in patients with ARDS, PEEP-titration to achieve an end-expiratory transpulmonary pressure (Ptp; PEEP – oesophageal pressure) based on a Ptp FiO_2 scale resulted in higher PEEP and plateau pressure (P_{plat}) levels, with both improved oxygenation, and Crs compared with conventional PEEP-titration [138] (ARDSnet protocol). [139] There was a trend to improved mortality but the trial was small ($n = 61$), and clinical outcomes, not physiologic data, should drive decision making; comparing V_T of 6 versus 12 mL/kg pbw oxygenation was worse in the lower V_T , lower-mortality group for the first 3 days. [139] However, there continues to be strong interest in using transpulmonary pressure to guide mechanical ventilation in ARDS. [140]

Measurement of Elastance

Elastance and resistance are frequency-dependent, and respiratory mechanics depend upon the volume and volume history of the lung. [141] With the increasing frequency of breathing, total respiratory system resistance falls and elastance increases, and this is particularly obvious in patients with airflow obstruction. [142] , [143] Consequently, these factors must be taken into account when interpreting respiratory mechanics. In a passively ventilated subject, P_{ao} is the sum of (1) the pressure required to overcome airway, endotracheal tube and circuit resistance (P_{res}), (2) the elastic pressure required to expand the lung and CW (P_{el}), (3) the elastic recoil pressure at end expiration or total PEEP (P_o), and (4) the inertial pressure required to generate gas flow (P_{inert}):

$$P_{\mathrm{ao}} = P_{\mathrm{el}} + P_{\mathrm{res}} + P_{\mathrm{o}} + P_{\mathrm{inert}} \qquad \textbf{(38.6)}$$

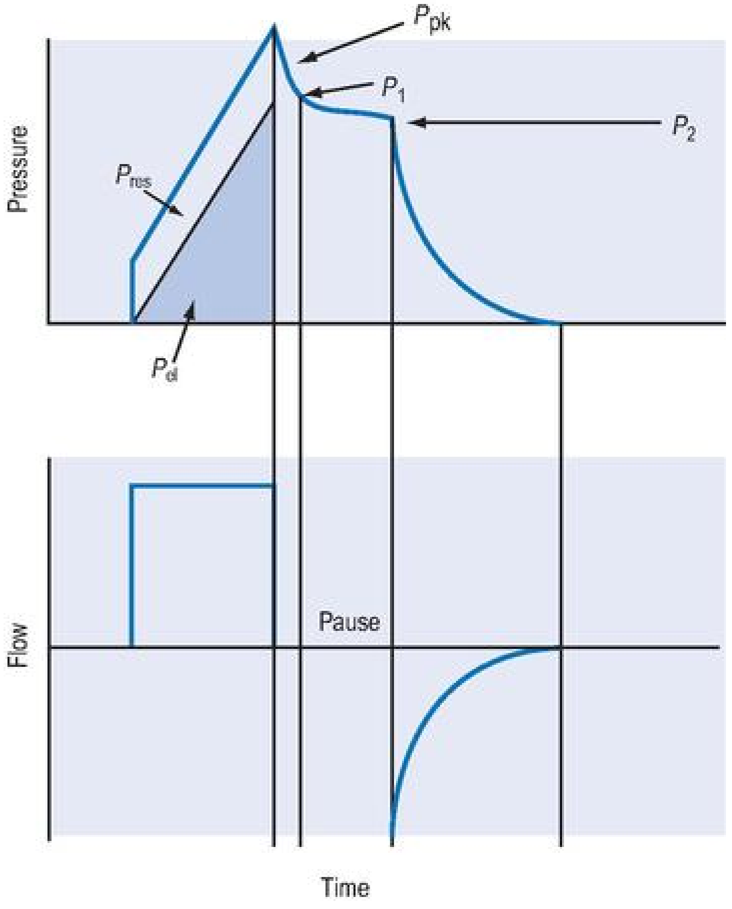
Since the elastance (E) is equal to $\Delta P/\Delta V$, with the resistance (R) equal to $\Delta P/\Delta \dot{V}$, and ignoring the inertance, [144] this can be rewritten as the single-compartment equation of motion:

$$P_{ao} = E_{RS}V + R_{RS}\Delta\dot{V} + P_o \qquad \textbf{(38.7)}$$

Elastance can then be measured using either static techniques, where cessation of gas flow allows dissipation of P_{res}, or dynamic techniques, where flow is not interrupted.

End-Inspiratory Occlusion Method

The simplest estimate of E_{RS} can be made using a rapid end-inspiratory airway occlusion during a constant flow breath, provided that the respiratory muscles are relaxed (Fig. 38.2). If a plateau is introduced at end inspiration, there is a sudden initial pressure drop due to dissipation of flow resistance ($P_{pk} - P_1$) followed by a slower, secondary pressure drop to a plateau ($P_{dif} = P_1 - P_2$) due to stress relaxation. At least 1–2 seconds are taken for this plateau to be achieved, and P_2 is often called the plateau pressure; however, if P_{plat} is measured too soon it will lie somewhere between P_1 and P_2.



The pair of graphs consists of two sections arranged vertically. The top graph plots pressure on the vertical axis against time on the horizontal axis. A curve on this graph rises sharply to a point labelled peak pressure, then drops slightly to a level labelled plateau pressure, and finally decreases to a baseline labelled expiratory pressure. The area between the curve and the baseline is shaded. The bottom graph also plots pressure on the vertical axis against time on the horizontal axis. A rectangular wave pattern on this graph rises to a constant level, maintains that level for a period labelled pause, and then drops back to the baseline.

FIG. 38.2 Schematic diagram of a volume-controlled breath with constant inspiratory flow. A period of no inspiratory gas flow has been interposed before expiration (pause) to illustrate dissipation of lung resistance as airways resistance (fall from P_{pk} to P_1) and tissue resistance (fall from P_1 to P_2). The inspiratory pressure due to the elastic properties of the respiratory system is illustrated in the top panel as the filled area (P_{el}), and the lung resistive pressure is labelled as P_{res}. (See text for more detail.)

Stress Adaptation

Stress relaxation of the respiratory system is due to both tissue viscoelasticity and time-constant inequalities of the respiratory system (pendelluft). In the normal lung, pendelluft has a minimal contribution to stress relaxation.[145] However, heterogeneity of regional resistance and elastance can markedly influence stress relaxation.[146] Pulmonary surfactant and its contribution to changes in surface tension, parenchymal factors including elastic fibres in the lung, contractile elements such as the alveolar duct muscle and changes in pulmonary blood volume have all been implicated in the viscoelastic properties of the lung. In the abnormal lung, it is difficult to separate either of these factors or the role of pendelluft in stress adaptation. However, pendelluft may contribute to lung injury in ARDS during triggered or supported ventilation.[147]

Calculation of Respiratory Mechanics

Returning to Fig. 38.2, it is now simple to estimate respiratory system resistance and elastance from P_{ao}. The static elastance ($E_{rs,st}$) and the dynamic elastance ($E_{rs,dyn}$) are calculated as:

$$E_{\mathrm{rs,st}} = \left(P_2 - P_{\mathrm{o}}\right) / V_{\mathrm{T}} \quad \textbf{(38.8)}$$

$$E_{\mathrm{rs,dyn}} = \left(P_1 - P_{\mathrm{o}}\right)/V_{\mathrm{T}} \qquad \textbf{(38.9)}$$

where P_{o} is the total PEEP (extrinsic plus intrinsic PEEP). The difference between $P_{\mathrm{el,dyn}}$ and $P_{\mathrm{el,st}}$ is the effective recoil pressure of the respiratory system during mechanical ventilation. Consequently, additional work is performed during inspiration to overcome stress adaptation, and this is stored and dissipated during expiration. This contributes to the hysteresis seen in dynamic volume–pressure curves during mechanical ventilation, and to the generation of expiratory flow. This latter component may be important in patients with air-flow obstruction since the imposition of a pause at end inspiration results in a 32% dissipation of the total energy loss within the respiratory system. [148]

The Static Volume–Pressure Curve

The quasistatic volume–pressure ($V - P$) curve is infrequently performed, and the relevance of a measurement performed on a single occasion is questionable when lung mechanics are not constant. Various techniques have been described, but the overall concept is that incremental volume and pressure points are made after a sufficient period of no flow has allowed P_{res} to be dissipated. This allows the definition of a sigmoidal-shaped curve with upper and lower inflection points, and a mid-section with relatively linear $V - P$ relations, allowing inflation elastance to be measured as this slope at a given lung volume. If similar measures are made during deflation, a deflation curve and its hysteresis can also be described.

The $V - P$ curve provides an advantage over an end-inspiratory elastance as, with the latter, it is not possible to know which part of the $V - P$ curve is being measured. Consequently, this ‘chord’ elastance may span either inflection point, yielding a falsely high figure. The upper inflection point represents a sudden decrease in elastance with increasing volume, and this has been interpreted as lung overdistention. The lower inflection point represents a sudden decrease in elastance with increased volume, and this has been interpreted as the recruitment of atelectatic air spaces. Ventilation between these two inflection points should minimise both shearing forces secondary to repetitive collapse and reopening of alveoli and overstretching of alveoli. However, this interpretation of the $V - P$ curve has been questioned. In patients with ARDS, recruitment occurs well above the lower inflection point, along the entire $V - P$ curve and above the upper inflection point.[149,150] An alternative interpretation is that the lower inflection point represents a zone of rapid recruitment, and that the upper inflection point is due to a reduced rate of recruitment.[151]

Conventionally the static $V - P$ curve has been measured in paralysed ventilated patients with the ‘super-syringe’ method.[152] In a paralysed patient, the RS is progressively inflated from FRC in 100 mL steps up to ~1700 mL or a predefined pressure limit. After each step, sufficient time is allowed for a well-defined plateau to become apparent (using a pause of 3–6 seconds). The effects of temperature, humidity, gas compression and ongoing gas exchange during the manoeuvre need to be taken into account,[153,154] and the volume history is standardised before it is performed. Many patients become hypoxaemic following disconnection from the ventilator during the 60 seconds or so without PEEP. An alternative is to randomly insert a range of single-volume inflations, followed by a prolonged pause,[155] during normal mechanical ventilation at 0 cm H_2O PEEP. Advantages include simplicity, the patient is not disconnected from the ventilator, the volume history is the same for each measurement and gas exchange during the measurement is negligible. However, again, many patients will become hypoxaemic due to prolonged periods without PEEP (this procedure may take ~15 minutes), particularly following a small-volume breath. Finally, an automated low-flow $V - P$ curve method allowing subtraction of P_{res} is available on some ventilators, takes around 20 seconds to perform, and correlates well with the static occlusion technique.[156,157]

The Dynamic Volume–Pressure Curve

Dynamic P_{ao}, $\dot{V}$ and V are displayed by many ventilators, but the volume signal is not referenced to FRC, and the signals are not readily available for quantitative analysis. However, $\dot{V}$ is readily measured with a heated pneumotachograph, and volume can then be derived by simple integration. If P_{ao} is also collected, it is relatively simple to measure dynamic mechanics.

The dynamic $V-P$ curve appears to show hysteresis, due to the effects of airway and tissue resistance; however, during tidal breathing even the static $V-P$ does not show hysteresis.[158] In contrast to static $V-P$ relations, dynamic mechanics are collected during normal ventilation so they do not interfere with patient care, and they provide a ‘functional’ description of respiratory mechanics. Indeed, the ‘effective’ alveolar distending pressure is more accurately $P_{\mathrm{el,dyn}}$, not $P_{\mathrm{el,st}}$. Since dynamic mechanics are potentially continuous, they could also be used to servo-control ventilatory strategies.

There are a number of ways to analyse dynamic $V-P$ data. A line can be drawn between no-flow points at end inspiration and end expiration to determine elastance; however, this is relatively inaccurate as it is based on two points that can be hard to exactly identify. Multiple linear regression analysis is now the technique most commonly employed. The patient does not need to be paralysed,[159] provided the respiratory muscles are not active during ventilation. The signal can also be split to allow analysis of inspiratory and expiratory mechanics.

Provided the model fit is acceptable, elastance and resistance are accurately and reproducibly calculated using the single-compartment equation of motion:

$$P_{\mathrm{ao}} = E_{\mathrm{RS}}\mathrm{V} + R_{\mathrm{RS}}\Delta\dot{V} + P_{\mathrm{o}} \tag{38.10}$$

Static intrinsic PEEP ($\mathrm{PEEP}_{\mathrm{i}}$) is accurately calculated, as $P_{\mathrm{o}} - \mathrm{PEEP}_{\mathrm{e}}$, when compared with either an end-expiratory airway occlusion method[160] or by direct measurement of end-expiratory alveolar pressure.[161] However, the single-compartment model only approximates the RS, and frequency and volume dependence of the derived mechanics are observed.

Changes in elastance during tidal breathing can be modelled with the stress index derived from power analysis of the $P_{ao} - t$ curve ($P_{ao} = a^t + c$), [162] and addition of a volume-dependent term to the equation of motion [124], [163]:

$$P_{\text{ao}} = (E_1 + E_2 V)\, V + R_{\text{RS}} \Delta \dot{V} + P_{\text{o}} \tag{38.11}$$

$$E_{\text{rs}} = E_1 + E_2 V \tag{38.12}$$

Since power analysis requires a constant inspiratory $\dot{V}$ pattern to discount resistive effects, it is not as versatile as the volume-dependent technique, which models resistance and can be applied to any inspiratory $\dot{V}$ pattern. Both measures correlate highly with each other, suggesting they measure the same parameter.

High stress, and possibly overinflation, is inferred when the stress index is greater than 1.1 and when the volume-dependent elastance increases, which may be quantified:

$$\%E_2 = 100 E_2 V / E_{\text{rs}} \tag{38.13}$$

A stress index below 0.9 and a negative volume dependence (negative $\%E_2$) suggest significant atelectasis during tidal breathing. Provided both V_T and $\dot{V}$ are constant, the change in driving pressure, either $P_{pk} - \text{PEEP}_{tot}$ or $P_1 - \text{PEEP}_{tot}$ 20–30 minutes following a change in PEEP, is highly correlated with $\%E_2$. [124] Using the 95% predictive interval for these data, an increase in $\Delta P > 2$ cm H_2O, consistent with a significant increase in elastance, suggests high stress and overinflation. Similarly, the lowest E_{rs} during PEEP-titration targets the best balance between recruitment and overinflation and may be superior to the stress index or $\% E_2$ in laboratory models. [164]

Both the stress index and volume-dependent elastance also vary with stress relaxation, and high stress may not mean overinflation; in COPD, bullous lung disease is due to a loss of lung tissue and elastic recoil. This may be measured on CT as hyperaerated; however, the associated wall stress may be high or low depending upon the degree of inflation.

Interpretation of Elastance

Elastance may be increased due to a reduction in lung volume or to an increase in specific elastance, the product of elastance and FRC. Small body size, female gender, lung resection and reduced aerated lung volume (e.g. ARDS) are important factors in reducing effective lung volume. Specific elastance is increased in ARDS, pulmonary oedema and pulmonary fibrosis.

Measurement of the Resistance of the Lung and Chest Wall

Lung resistance (R_L) is the sum of airway (R_{aw}) and tissue resistance (R_{ti}). Resistance is flow-, volume- and frequency-dependent, and R_L decreases as f increases. It is also important to compare measurements at similar lung volumes since there is a hyperbolic relation between lung volume and R . This is particularly obvious in ARDS, where the incremental administration of PEEP can result in a decrease in R_{aw} due to concurrent recruitment and an increase in lung volume. Indeed, although the absolute values are increased, when corrected for EELV R_L , R_{aw} and R_{ti} are unchanged in ARDS, [126] although specific R_{ti} did increase with PEEP. [130] Finally, since gas flow may be a mixture of laminar and turbulent flow, resistance is often flow-dependent.

End-Inspiratory Occlusion Technique

The total inspiratory R_{aw}, including the endotracheal tube and associated ventilatory apparatus, can be calculated in a relaxed patient following an inspiratory pause (see Fig. 38.2) as:

$$R_{\mathrm{aw}} = (P_{\mathrm{pk}} - P_1)/\dot{V} \tag{38.14}$$

and R_L was calculated by using P_2 instead of P_1. Since the endotracheal tube and apparatus will make a significant contribution to R_{aw}, it is best to measure P_{ao} distal to the endotracheal tube with an intratracheal catheter. An alternative approach is to calculate and subtract endotracheal tube resistance using the Rohrer equation ($R = K_1 + K_2 \dot{V}$), [165] and this is now automatically included in some ventilators. However, as in vivo endotracheal tube resistance is often greater than in vitro resistance [166] due to the effect of secretions and interaction with the tracheal wall, these corrections may be inaccurate. Despite these provisos, this simple measure of resistance, or the P_{pk} to P_{plat} difference at a constant $\dot{V}$, can be clinically useful in both the diagnosis and monitoring of air-flow obstruction. [167]

Dynamic Techniques

Total, inspiratory and expiratory R can also be estimated, using either multiple linear regression analysis or from linear interpolation of the $V-P$ curve at a constant volume. However, this latter technique assumes a constant elastance during tidal inflation and may be inaccurate because it relies on only two measurements. Finally, an average expiratory R can be calculated from the time constant (τ) derived from passive expiration if the E is known, since:

$$\tau = R/E \tag{38.17}$$

However, the lung does not empty as a single compartment in patients with air-flow obstruction, and E is assumed to be constant over the tidal expiration.

Other Measurement Techniques

The interrupter technique consists of a series of short (100–200 ms) interruptions to relaxed expiration by a pneumatic valve.[168] This results in an expiratory plateau in P_{ao} following equilibration with alveolar pressure. From the V, P and $\dot{V}$ data, the expiratory elastance and the expiratory P–$\dot{V}$ relationship are measured. This technique does not make assumptions about the behaviour of the RS and can identify dynamic air-flow limitations.

Assuming that the respiratory system behaves linearly, it can be analysed following a forced-flow oscillation at the airway opening.[169] The resultant pressure waveform depends upon the impedance of the RS, which can be analysed following Fourier analysis of the P and $\dot{V}$ waveforms into resistance and reactance. This will then allow measurement of R_{aw}, R_{ti}, E_{rs} and inertance, and information can be gained regarding small airways disease by examining R_{aw} at different oscillatory frequencies.

Forced Expiratory Flow

Maximum expiratory flow rates from TLC, the forced vital capacity (FVC), the forced expiratory volume in the first second of expiration (FEV_1) and the peak expiratory flow rate (PEFR) are commonly measured in cooperative subjects with a spirometer or flow meter. The PEFR is cheap but is relatively effort-dependent, and is less specific and reliable than the FEV_1. It is most useful for office or home use. The normal PEFR is 450–

700 L/min in males and 300–500 L/min in females. It is reduced with obstructive diseases and gross muscle weakness.

The FEV_1 is usually expressed as a ratio of the FVC since both may be reduced in restrictive disease, with a normal ratio. The FEV_1 is normally 50–60 mL/kg and 70%–83% of FVC. In asthma and COPD, the FEV_1 is reduced out of proportion to the FVC to a ratio of less than 70%.

Measurement of Intrinsic Positive End-Expiratory Pressure

$PEEP_i$ (1) may have unrecognised haemodynamic consequences, [170] (2) adds an elastic load to inspiratory work during assisted and supported ventilatory modes, which may be reduced by application of small amounts of $PEEP_e$, [171] and (3) reflects dynamic hyperinflation with the consequent risks of barotrauma [172] and right heart failure. If $PEEP_i$ is not taken into account during the calculation of chord compliance, an incorrect denominator is used, which may result in gross error. [173] As automated measures of mechanics do not account for $PEEP_i$, estimates of elastance must be corrected.

The two most commonly described techniques for measuring $PEEP_i$ are end-expiratory airway occlusion in a relaxed subject and the fall in oesophageal pressure during inspiration prior to initiation of inspiratory $\dot{V}$. However, these are not really comparable measures since static and dynamic $PEEP_i$, respectively, are measured. Static $PEEP_i$ is measured as the plateau P_{ao} that is reached following an end-expiratory occlusion; typically, a plateau is reached in ~5 seconds, but this will be shorter in ARDS and longer in severe COPD. With the cessation of gas flow, alveolar pressure equilibrates with P_{ao}. Since the lung is composed of non-homogeneous units, this will represent the average static $PEEP_i$. All respiratory effort must be absent since muscle pressure will increase end-expiratory P_{ao}. End expiration must be accurately identified. This is most easily done by the ventilator itself either using an end-expiratory hold manoeuvre or by using the next inspiration, the onset of which is concurrent with expiratory valve closure, to close a valve that directs inspiratory flow to atmosphere and seals the circuit. Static PEEP $_i$ is a surrogate measure of dynamic hyperinflation, and this volume may be directly measured using a spirometer [170] or a pneumotachograph [124] during a prolonged expiration.

Dynamic PEEP $_i$ is measured as the pressure change required to initiate inflation. In ventilated subjects, this will be the change in P_{ao} prior to initiation of inspiratory $\dot{V}$, [171] and in spontaneously breathing subjects the change in oesophageal [169] or transdiaphragmatic [174] pressure from their end-expiratory relaxation values prior to inspiratory $\dot{V}$. Measurement of dynamic PEEP $_i$ in spontaneously breathing subjects is not particularly straightforward. The changes in pressure are small and influenced by cardiogenic oscillations, which are preferably filtered out. [175] Furthermore, dynamic PEEP $_i$ is not constant, with breath-to-breath variation probably due to variations in the extent of dynamic hyperinflation. Many patients with air-flow obstruction have an active expiration that ‘falsely’ increases PEEP $_i$, at least with respect to its elastic load since cessation of active expiration does not require work. [176] Consequently, it is preferable to concurrently measure intragastric pressure as a measure of active expiration.

Finally, PEEP $_i$ can be measured as P_o from dynamic P, V and $\dot{V}$ data in ventilated subjects. This is thought to be a measure of dynamic PEEP $_i$ since static PEEP $_i$ systematically yields a slightly greater result, [160] with similar discrepancies reported between other dynamic measures of PEEP $_i$ and static PEEP $_i$. [177], [178] This systematic difference correlates with, and is thought to be due to, the viscoelastic properties and regional time constant inequalities of the respiratory system. [177] This has clinical significance as, although matching dynamic PEEP $_i$ with PEEP $_e$ reduces respiratory work through a decrease in elastic load, [171] it does not counterbalance these forces.

Patient–Ventilator Asynchrony

Asynchrony between the patient and ventilator is more common than usually recognised during both intubated and non-invasive ventilatory support, and is often due to patient effort failing to trigger the ventilator. Clinical findings include agitation and anxiety, tachycardia, tachypnoea and increased work of breathing. Careful observation of the patient–ventilator interaction, including waveforms, can be used to further identify and help match ventilatory assistance to neural drive [179] (see also Chapter 31).

Inspiration

Triggering of Inspiration

Ineffective respiratory efforts are best detected from the P_{es} waveform; however, this is rarely monitored. Ineffective triggering due to PEEP_i may be detected from the expiratory $\dot{V}$ waveforms as an abrupt decrease in $\dot{V}$ at either the onset of inspiratory muscle activity or relaxation of the expiratory muscles. Monitoring of P_{ao} is less sensitive unless the circuit expiratory resistance is increased (e.g. heat and moisture exchanger [HME] or poorly functioning expiratory valve) so that small changes in expiratory $\dot{V}$ are reflected in P_{ao} . Sensing P_{ao} at the Y-piece may not offer any advantage, as the pressure signal needs to travel the same distance, usually via separate gas tubing to the ventilator expiratory block. Inadequate sensitivity may also lead to ineffective triggering with similar but more obvious waveform effects.

Autotriggering, a triggered assisted or supported breath without patient effort, may occur owing to excessively low trigger threshold or to P_{ao} or $\dot{V}$ distortion, as commonly seen with large cardiogenic oscillations, hiccups, condensate in tubing or a circuit leak. Again, waveform analysis may help detect and manage the problem; for example it may be necessary to reduce trigger sensitivity to prevent cardiogenic oscillations from being detected as inspiratory effort.

Inspiration

During an assisted volume control breath, P_{ao} may fall, often seen as a scalloped shape, if there is excessive inspiratory muscle effort as seen in $\dot{V}$ starvation. Expiratory muscle effort, as may be seen with an excessive V_T or prolonged inspiratory time (T_i), leads to a rise in P_{ao} . During an assisted pressure control breath or during pressure support, changes in patient effort are detected from the $\dot{V}$ waveform. Finally, excessively rapid development of the set delivered pressure, a rapid rise time, may be detected by an overshoot in P_{ao} ; an excessively long rise time will be seen as a rounded inspiratory $\dot{V}$ profile, similar to that seen with continued inspiratory muscle effort.

Cessation of Inspiration

Mismatch of the mechanical and neural T_i can be detected from waveform changes at the cessation of inspiration.

Mechanical T_i Shorter than Neural T_i

There will be prolonged inspiratory muscle effort during early expiration; if this leads to a sufficient fall in P_{ao} or $\dot{V}$, an early triggered breath follows. During pressure-cycled ventilation, this will lead to a second small I_T breath due to the high baseline lung volume, but in assist volume control P_{ao} will be excessive. Typically, this is seen with a stiff respiratory system, $PEEP_i$ or inadequate pressure support.

Mechanical T_i Longer than Neural T_i

This leads to features of passive inflation such as a linear increase in P_{ao} during assist volume control ventilation; during pressure-cycled ventilation, there may be an increase in P_{ao} due to loss of inspiratory effort, or an unexplained fall in $\dot{V}$.

Expiration

Changes in P_{ao} during expiration are usually small unless expiratory circuit resistance is abnormally high. However, in patients with expiratory flow limitation, the expiratory $\dot{V}$ waveform shows a typical ‘tick’ pattern; there is a rapid spike in expiratory flow due to dynamic compression of large conducting airways at the beginning of expiration, and this is followed by low, slowly declining expiratory $\dot{V}$ due to high $\dot{V}$ expiratory resistance. When $PEEP_i$ is present, the expiratory $\dot{V}$ fails to cease prior to the inspiratory trigger; however, this may be difficult to detect due to the poor fidelity present on most commercial ventilators.

Monitoring Neuromuscular Function

Inspiratory Occlusion Pressure

The pressure of 100 ms (P_{100} or $P_{0.1}$) after a random occlusion timed at the beginning of inspiration is a measure of respiratory drive. There is a large range of normal values (1.5–5 cm H_2O), but it is reproducible in an individual patient. In ventilated patients, the $P_{0.1}$ correlates with the work of breathing during pressure support ventilation, and changes in the same direction as $PEEP_e$ are increased if work is reduced.[180] Consequently, $P_{0.1}$ may prove to be a useful method of titrating $PEEP_e$ in patients with dynamic hyperinflation; however, this is not valid when flow triggering is used.

Maximum Mouth Pressures

Maximum inspiratory (MIP) and expiratory (MEP) mouth pressures can be used to estimate the power of the respiratory muscles. MIP is usually measured in ventilated patients using a unidirectional expiratory valve for ~20 seconds.[181] This ensures the procedure is performed from a low lung volume and does not require patient cooperation. However, despite this, the results are quite variable.[182] Normal values vary with age and gender; young females may exceed ~−90 cm H_2O, and young males ~−130 cm H_2

O. A MIP ≤ 20 cm H_2O is predictive of weaning failure; however, this is associated with too many false positives and negatives to be useful.[122] MEP may be useful in myopathic patients with expiratory muscle weakness. Transdiaphragmatic pressure is assessed using an oesophageal and gastric balloon to measure the pressure in these two cavities.

Work of Breathing

The work of breathing (W_B) is the sum of elastic work (W_{el}), flow-resistive work (W_{res}) and inertial work (negligible), and can be estimated from V–P data during spontaneous or assisted ventilation. An oesophageal balloon is used to examine changes in pleural pressure, $\dot{V}$ is measured with a pneumotachograph and volume is derived as its integral. Although conceptually W_B is the inspiratory area of a V–P loop, this needs to be referenced to the CW V–P curve, and the appropriate area measured from a Campbell diagram.[183]

The normal W_B is ~0.5 J/L of $\dot{V}_E$, and this may be significantly increased in patients with acute respiratory failure, and by additional work imposed by ventilatory apparatus, including the endotracheal tube and connector, humidifier and ventilator circuit.[184] The consequences of a large increase in W_B may include an increase in the $\dot{V}O_2$ attributable to breathing ($\dot{V}O_{2resp}$), respiratory muscle insufficiency, CO_2 retention and acute respiratory failure. However, W_B is rarely measured outside of research projects since the Campbell diagram is a relatively tedious approach. Simplifications have been used, but these are not as accurate, and W_B only estimates energy expenditure during muscle shortening with relatively poor correlation with $\dot{V}O_{2resp}$.[185] Consequently, the pressure–time product (PTP), which does correlate with $\dot{V}O_{2resp}$,[186] is more commonly measured.[106]

Pressure–Time Product (PTP)

PTP is usually calculated from the oesophageal pressure–time integral during inspiration. In mechanically ventilated patients, the oesophageal pressure during assisted breathing is compared with that during a controlled breath, or that pressure calculated from the CW elastance and lung volume.[106] However, the early correlation of $\dot{V}O_{2resp}$ with PTP used the transdiaphragmatic pressure in spontaneously breathing subjects.[183] Using either technique, importantly, the effort expended before $\dot{V}$ occurs due to PEEP$_i$ is measured, probably accounting for the better correlation of $\dot{V}O_{2resp}$ with PTP than W_B.[183] Although incremental pressure support ventilation may reduce PTP in COPD patients, the effect can be variable with some patients also showing evidence of expiratory muscle activity due to delayed sensing of neural expiration.[106]

Electrical Activity of the Diaphragm

Using a modified nasogastric tube, electrical activity of the diaphragm (EAdi) can be monitored and used to drive neutrally assisted ventilation.[187] While EAdi and transdiaphragmatic pressure (Pdi) usually show a strong correlation, suggesting that EAdi could replace the need for P_{es} monitoring in some circumstances, electromechanical uncoupling may occur when the diaphragm is placed under mechanical disadvantage such as the presence of PEEPi.[140] During triggered ventilation, EAdi may help diagnose and manage asynchrony, and this technique offers assistance in diagnosing and managing neuromuscular disorders, particularly those with minimal peripheral muscle manifestations.

Ultrasound

Lung ultrasound is covered in Chapter 40 . Ultrasound can also be used to measure diaphragm thickness at the zone of apposition; additional uses include description of function, asynchrony and prognostication. For example fractional thickening of the diaphragm was predictive of weaning trial outcome.[188] The measurement technique does take skill, and a recent

Delphi consensus described agreed measurement parameters and future directions. [189]

Troubleshooting mechanical ventilation waveforms

David V. Tuxen and Paul Nixon

Most mechanical ventilators have a display screen that, amongst many other variables, can show the waveforms of the two primary measurements from the ventilator circuit – airway pressure and flow. Most other measurements such as tidal volume, flow volume and pressure volume graphs are derived from these two primary measurements.

Many problems that are clinically important to patient care can be derived from careful and systematic observations of the ventilator waveforms. This can lead to diagnoses that may not otherwise be apparent and also to the recognition of problems that require treatment.

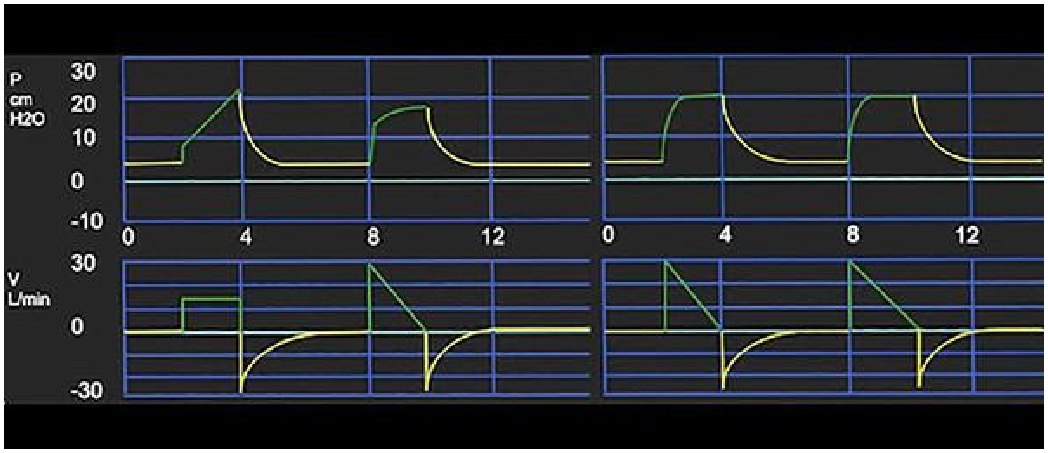
Waveform variations are commonly not recognised by clinicians and if they are, the cause of the problem and its solution are not always known. Failure to understand waveform variations, some of which are erroneously termed ‘patient dyssynchrony’ can lead to the unnecessary use of increased sedation and even paralysis to ensure that the patient ‘fits’ the desired ventilator setting.

Airflow obstruction is important clinically and should be recognised. Lower or small airway obstruction (LAO) should be discriminated from upper or large airway obstruction (UAO), as these require quite different management strategies. Disrupted inspiratory pressure and flow patterns as a result of patient effort (termed M-waves as that is their usual shape) need to be recognised, diagnosed and managed. Common examples include flow starvation, volume starvation and reverse triggering. There are a number of other recognisable waveform abnormalities that are disruptive to ventilator function, patient comfort and patient-ventilator synchrony, such as self-cycling and missed inspiratory efforts.

A. Normal Ventilator Waveforms

The appearance of normal ventilator waveforms will depend on the ventilation mode being used and the inspiratory flow profile (Fig. 39.1). Regardless of the mode, a systematic 6-point assessment of the pressure and flow waveforms can be used to aid in the diagnosis of waveform abnormalities (Fig. 39.2)

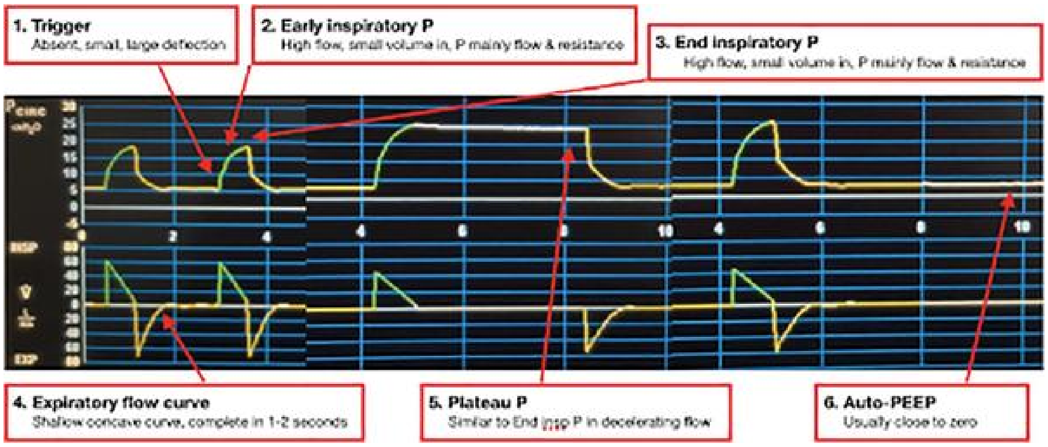
1. Initiation of inspiration, was the breath triggered?
2. The early inspiratory pressure
3. The end-inspiratory pressure
4. The shape of the expiratory flow curve
5. Plateau pressure measurement (end-inspiratory hold manoeuvre)
6. Auto-PEEP measurement (end-expiratory hold manoeuvre)



The graph presents four waveforms that measure respiratory parameters over a period of twelve seconds. The graphs are arranged in two columns, with two graphs on the left and two on the right. The top two graphs measure pressure in centimetres of water on the vertical axis, which ranges from negative ten to thirty in increments of ten, and time in seconds on the horizontal axis, which ranges from zero to twelve in increments of four. The waveform fluctuates between ten and twenty centimetres of water. The bottom two graphs measure volume in litres per minute on the vertical axis, which ranges from negative thirty to thirty in increments of ten, and time in seconds on the horizontal axis, which ranges from zero to twelve in increments of four. The waveform fluctuates between negative ten and ten litres per minute. Each graph includes a horizontal line at the zero mark on the vertical axis to indicate the baseline.

FIG. 39.1 Pressure-time and flow-time simulated waveforms in a VCV mode. The first breath is delivered with a constant or square wave inspiratory flow profile. The x-axis is time in seconds. The second breath has a decelerating inspiratory flow profile. The 3rd and

4th breaths are pressure-time and flow-time simulated waveforms in a PCV mode.



The graph presents six stages of a respiratory cycle through waveforms, labelled from one to six. The first stage, labelled trigger, includes absent, small, or large deflection. The second stage, labelled early inspiratory pressure, describes high flow, small volume, primary flow, and resistance. The third stage, labelled end inspiratory pressure, indicates high flow, small volume, primary flow, and resistance. The fourth stage, labelled expiratory flow curve, notes a shallow curve that completes in one to two seconds. The fifth stage, labelled plateau pressure, describes a similar end-inspiratory pressure to peak pressure in a decelerated flow. The sixth stage, labelled positive end expiratory pressure, notes a usual positive end expiratory pressure close to zero. Each stage includes a waveform that fluctuates across a grid, where the horizontal axis represents time and the vertical axis represents pressure or flow.

FIG. 39.2 This shows the systematic 6-point waveform assessment plan for a patient in VCV with decelerating inspiratory flow. The x-axis is time in seconds.

Volume Control Ventilation (VCV) with Constant (Square Wave) and Decelerating Inspiratory Flow Patterns

If a constant inspiratory flow (V_i) is used, the P_{aw} component spent on airway resistance remains relatively constant throughout inspiration. Hence the P_{aw} will rise in parallel with the alveolar pressure. The slope of this curve will represent the respiratory system compliance (V / P). The plateau pressure (P_{pl}) which approximates alveolar pressure can be measured with an inspiratory hold manoeuvre. In patients with normal airway resistance, there is usually a small drop in pressure from the peak inspiratory pressure to the P_{pl} (peak-to-plateau gradient). This pressure drop equates to the pressure spent on constant inspiratory flow and can be used to calculate inspiratory airway resistance.

With a decelerating V_i pattern, during the first half of inspiration, the V_i is high with only minimal tidal volume (V_t) delivered. As a result, most of the airway pressure (P_{aw}) is dependent on the inspiratory flow rate against the resistance produced by both the ventilator circuit and the patient's airways. By the end of inspiration, when the inspiratory flow has become very low or zero, the airway pressure is mainly dependent on the delivered V_t and the patient's respiratory system compliance. In patients with normal airway resistance, the early P_{aw} is usually lower than the end-inspiratory P_{aw} . As there is minimal flow at the end of inspiration the peak-to-plateau gradient should be close to zero.

Pressure Control Ventilation (PCV)

During PCV, the airway pressure rises to the set pressure and is maintained throughout the inspiratory period and is, therefore similar in early and end inspiration.

The expiratory flow curve is independent of the mode of inspiration, but instead dependent on the elastance and the resistance of the respiratory system. This is normally a shallow concave curve which returns to 0 flow within 1 to 2 seconds, depending on the V_t and the age of the patient. The area under the inspiratory flow-time curve represents the inspired V_t. The area above the expiratory flow-time curve represents the expired V_t and should approximate the inspiratory volume. Once the expiratory flow has returned to 0, it will remain at that level until the next breath is initiated. There are often small fluctuations in this curve when the flow is zero due to cardiac pulsation. This can be checked by determining if the fluctuations are in time with the cardiac rhythm.

B. Airflow obstruction

Sometimes, intubated ventilated patients can arrive in the ICU without much knowledge of their past history or details beyond their presenting complaint. Unrecognised severe airflow obstruction can lead to a lack of appropriate treatment and inappropriate ventilator settings.

Airflow obstruction can lead to

1. Increased inspiratory P_{aw} in VCV.
2. Reduced flow during expiration and abnormal expiratory waveform shape.
3. Persisting flow at the end of expiration.
4. Increased auto-PEEP.
5. Dynamic hyperinflation with risk of hypotension and barotrauma.

In decelerating flow VCV in patients with increased airway resistance and normal compliance, the early P_{aw} is higher than the end-inspiratory P_{aw}. This is because significant pressure is required to maintain flow against the high airway resistance during early inspiration. This leads to a raised peak-to-plateau gradient (Fig. 39.3).

The medical monitor screen contains respiratory data of a patient recorded on April eighth, two thousand eight, at twelve twenty one. The top section of the screen lists numerical values for various respiratory parameters. From left to right, these values include peak pressure at six point nine centimetres of water, positive end expiratory pressure at zero point nine centimetres of water, inspiratory to expiratory ratio at one point five seven, tidal volume at three hundred seventy five millilitres and total frequency at five point two five breaths per minute. Below these numbers, two graphs plot waveforms over time. The upper graph tracks airway pressure while the lower graph monitors airflow. The left side of the graphs includes a scale with numerical markers for measurement. At the bottom of the screen, several buttons with icons appear for control options on the monitor.

FIG. 39.3 VCV with a decelerating inspiratory flow profile in a patient with severe LAO. Note the pressure is higher in early

inspiration compared to end inspiration. Also, note the deep concave curve in expiration.

Lower Airway Obstruction (Small Airways)

The presence and severity of small airway obstruction due to COPD, asthma or other small airway obstruction conditions are usually detected on ventilator waveforms by four variables.

1. An early P_{aw} that is higher than the end-inspiratory P_{aw} (in VCV mode with decelerating inspiratory flow). This leads to an increased Peak-to-plateau gradient (Fig. 39.4).
2. Expiratory flow has a characteristic deep concave curve expiratory flow curve.
   The depth of the concavity is proportional to the severity of the airflow obstruction.
   This complex exponential curve is due to two factors. Small airway diameter changes in parallel with lung volume so that airway resistance is lowest at the end of inspiration and increases throughout expiration. Secondly, in moderate to severe small airway disease, airflow obstruction is usually non-uniform – more severely obstructed airways sequentially close off completely during expiration, resulting in a much smaller percentage of lung units with lesser degrees of airflow obstruction still having expiratory flow towards the end of expiration (Fig. 39.5).
3. Presence of end-expiratory flow representing failure to exhale trapped gas.
4. Presence of auto-PEEP (Fig. 39.4).

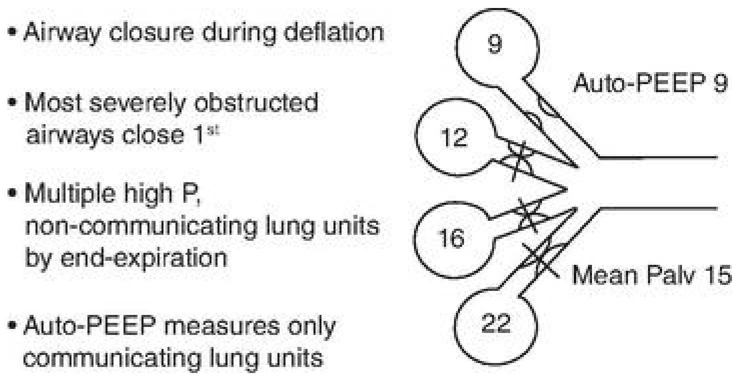
The medical monitor screen contains two side-by-side sets of respiratory data of a patient on April fourth two thousand eight. The left set corresponds to thirteen minutes past midnight and the right set to fourteen minutes past midnight. Each set lists numerical values at the top. For the left set, from left to right, the values include peak pressure at ten point one centimetres of water, positive end expiratory pressure at one point five seven, inspiratory to expiratory ratio at one point three, tidal volume at three hundred eighty three millilitres and total frequency at four point eight nine breaths per minute. For the right set, the values include peak pressure at eleven centimetres of water, positive end expiratory pressure at one point five seven, inspiratory to expiratory ratio at one point three, tidal volume at three hundred eighty four millilitres and total frequency at four point seven two breaths per minute. Below these numbers, each set features two graphs. The upper graph in each set represents airway pressure, and the lower graph represents airflow. The left side of each graph includes a scale with numerical markers for measurement. Several buttons with icons appear for control options at the bottom of the monitor.

FIG. 39.4 (A) Plateau pressure measurement with end-inspiratory pause. Note significant peak-to-plateau pressure gradient seen in airway obstruction. (B) Auto-PEEP measurement with end-expiratory hold manoeuvre. Note the significant rise in auto-PEEP seen in airway obstruction.



• Airway closure during deflation
• Most severely obstructed airways close 1st
• Multiple high P, non-communicating lung units by end-expiration
• Auto-PEEP measures only communicating lung units

The diagram explains lung mechanics with a focus on airway closure and pressure dynamics. A branched structure represents airways and lung units. The text lists key points in a vertical sequence. The first point states that airway closure occurs in deflation. The second point notes that the most severely obstructed airways close first. The third point describes multiple high-pressure noncommunicative lung units. The fourth point mentions that positive end-expiratory pressure measures only communicative lung units. Alongside the branched structure, labels indicate specific pressure values. One label near the top right reads positive end-expiratory pressure nine. Another label further down on the right reads mean alveolar pressure fifteen. Additional labels on the branches include nine, twelve, sixteen and twenty two which represent pressure values in different lung units.

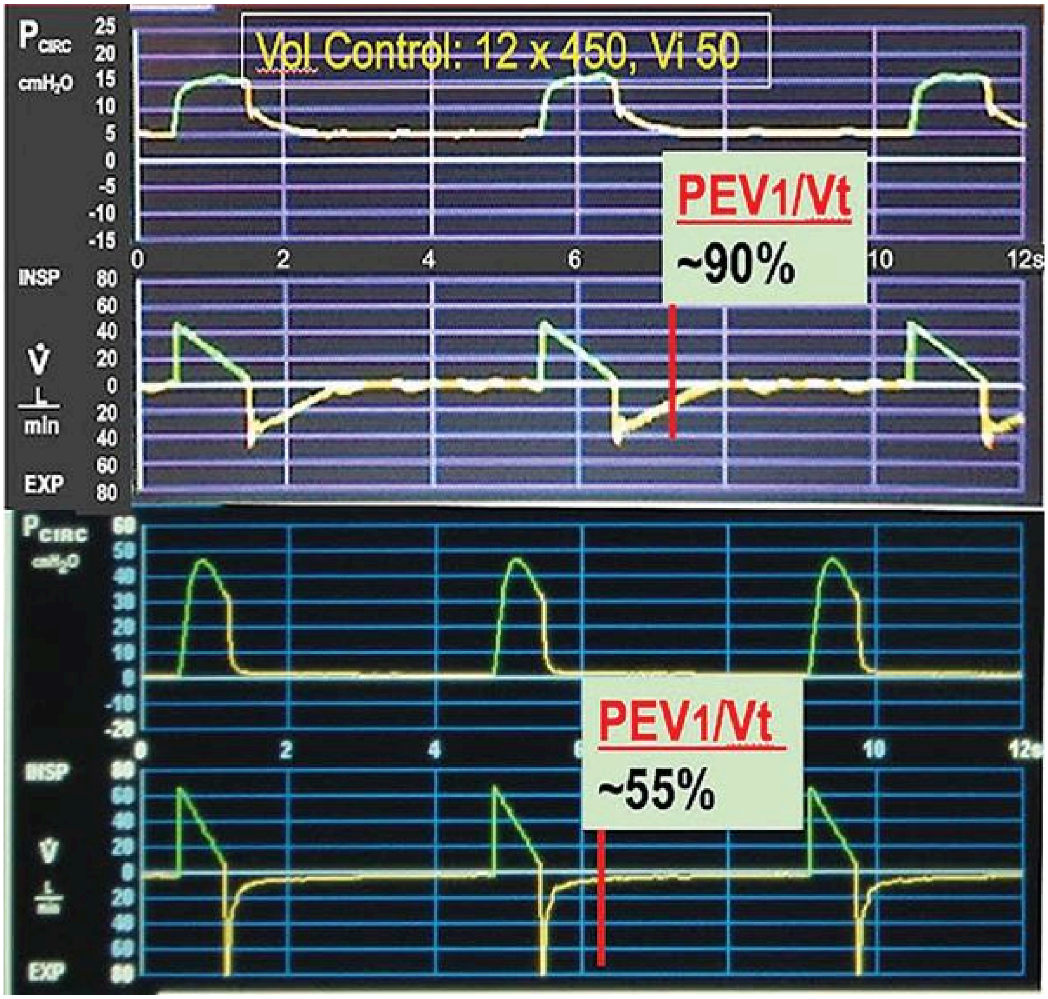
FIG. 39.5 Graphic demonstration of the sequential closure of more obstructed lung units throughout expiration, resulting in only the lower resistance, lower pressure lung units still deflating at the end of expiration to give the auto-PEEP measurement.

Unfortunately, many of these measurements are flawed, particularly in severe diseases.

The characteristic deep concave curve of expiratory flow has no routine quantification. The end-expiratory flow in very severe airflow obstruction may be so low that it appears to be zero. In this setting, the low end-expiratory flow (not a higher level of end-expiratory flow) represents worse airflow obstruction with higher auto-PEEP. Furthermore, the presence of end-expiratory flow is also breath rate dependent. Even in healthy patients, expiratory times (t_e) <1–1.5 seconds with respiratory rates ≥30 will commonly have the presence of end-expiratory flow, simply because there is insufficient time for V_t to be exhaled even with normal expiratory flows.

The presence of auto-PEEP >2 cm H_2O alerts to the presence of airflow obstruction but underestimates the severity of gas trapping and is insensitive to change. [1] Furthermore, it cannot be measured following an assisted or spontaneous breath as the patient will terminate the manoeuvre.

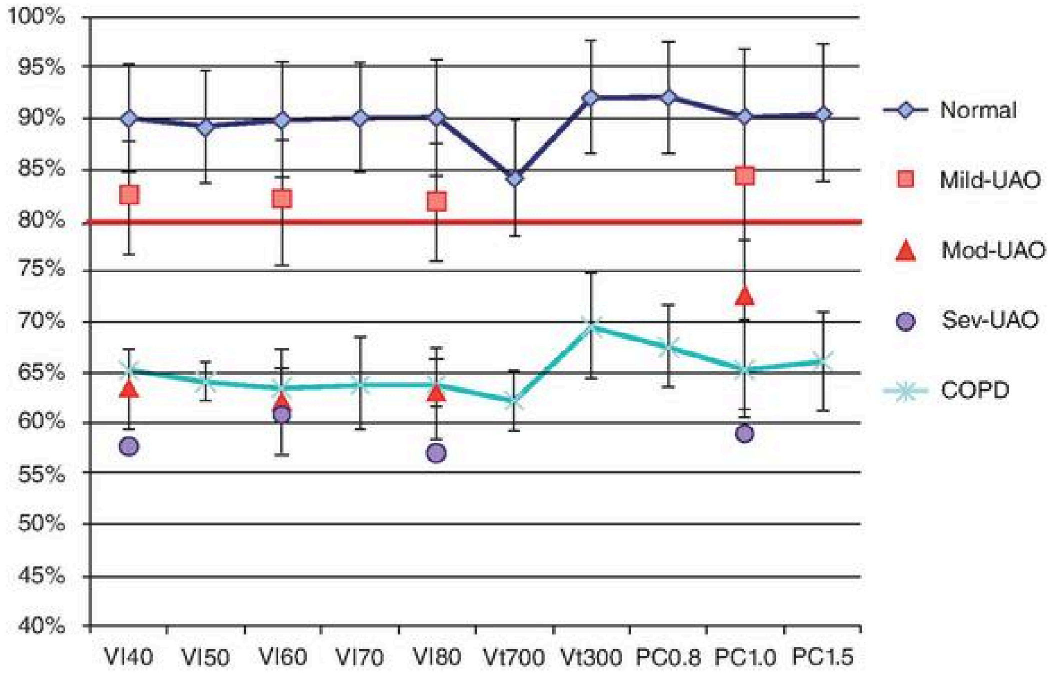
The usual way to quantify the severity of airflow obstruction in non-ventilated patients is by spirometry (the FEV1/VC ratio). A similar variable during mechanical ventilation is the passively expired volume during the first second of expiration (PEV1) expressed as a percentage of V_t (PEV1/ V_t ratio). This is an alternative reliable value to quantify the severity of airflow obstruction during mechanical ventilation and is sensitive to change (Fig. 39.6).



The medical monitor screen contains two graphs of respiratory data. The top graph has a label at the top that reads volume control, twelve times four hundred fifty volume index sixty. The graph plots airway pressure on the vertical axis labelled airway pressure centimetres of water, against time on the horizontal axis. The vertical axis ranges from negative fifteen to twenty five centimetres of water. A label within the graph reads positive end expiratory volume one to tidal volume negative ninety percent. The bottom graph plots airflow on the vertical axis labelled airflow litres per minute, against time on the horizontal axis. The vertical axis ranges from negative twenty to sixty litres per minute. A label within this graph reads positive end expiratory volume one to tidal volume, approximately fifty five percent. Both graphs have a time scale on the horizontal axis marked from zero to twelve seconds.

FIG. 39.6 Comparison of the passive expired volume (PEV1) expressed as a % of V_t (PEV1/ V_t %) between a ventilated patient with no airflow obstruction and a patient with severe airflow obstruction. The area under the Insp-Flow time curve gives a visual estimate of volume. The area above the Exp-Flow time curve during the first second gives a visual estimate of PEV1.

This has been studied in patients requiring mechanical ventilation for COPD and in ventilated patients where we have induced upper airway obstruction (Fig. 39.7). We found it to be reliable at detecting and quantifying airflow obstruction. The normal value is 90% of V_t expired in the first second of expiration, but a value of 80% is best used to clearly discriminate between variations of normal and definite airflow obstruction.



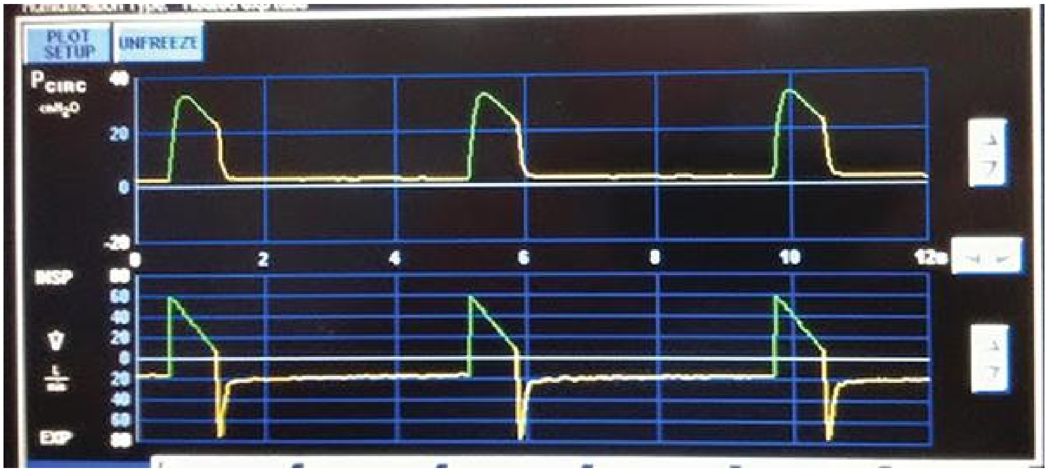
The graph presents oxygen saturation levels across five groups. The vertical axis represents oxygen saturation in percentage, which ranges from forty percent to one hundred percent. The horizontal axis lists volume and pressure setups from left to right. Five distinct data sets correspond to different conditions. The first set labelled normal ranges between eighty five percent and ninety five percent. The second set, labelled mild upper airway obstruction, stays around eighty percent. The third set, labelled moderate upper airway obstruction, fluctuates between sixty percent and seventy percent. The fourth set, labelled severe upper airway obstruction, hovers around sixty percent. The fifth set, labelled chronic obstructive pulmonary disease, remains steady near sixty five percent. Each data point includes error bars to indicate variability.

FIG. 39.7 **PEV1/ V_t values (mean ± SD) from ventilated patients, 11 without airflow obstruction (8.0 mm ETT) and 10 patients with severe COPD. Both groups were ventilated V_t 500 mL with V_i 40, 50, 60, 70 and 80, then V_t 700 and 300 with V_i 60, then PVC with Ti 0.8 s, 1.0 s and 1.5 s.** Mild, moderate and severe UAO was then introduced to the normal group with 2, 3 and 6 mm cannulae inside the 8.0 mm ETT. Normal PEV1/ V_t was 90 ± 5% for this range of V_{ts} . A lower limit of normal PEV1/ V_t of 80% included 97% of all normal measurements for this common range of ventilator settings.

Recognition of LAO is important as it may require adjustment of the ventilator settings to reduce dynamic hyperinflation (see Chapter 45) and usually the delivery of appropriate bronchodilator therapy. Measuring the PEV1/ V_t ratio may show a response to bronchodilators if successful.

Upper Airway Obstruction

Upper airway obstruction often goes unrecognised and like LAO can lead to dynamic hyperinflation, under ventilation and even barotrauma. Misdiagnosis may lead to the mistaken use of bronchodilators and failure to manage the cause of the airflow obstruction. Recognition is essential and sometimes requires urgent action. UAO can be due to a mechanical obstruction in the ventilation circuit or to patient pathology (Fig. 39.8).

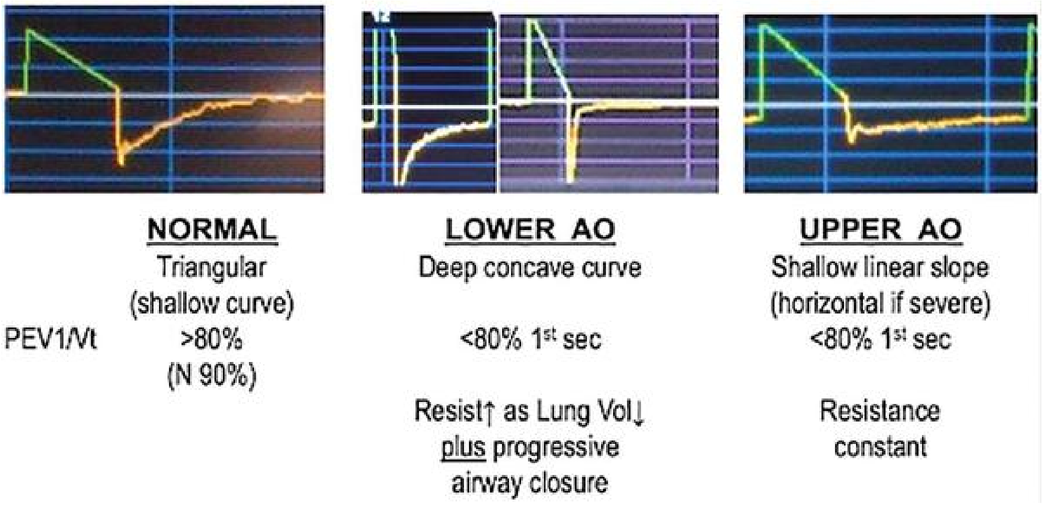


The medical monitor screen contains two graphs of respiratory data. The top graph plots airway pressure on the vertical axis, labelled airway pressure centimetres of water against time on the horizontal axis. The vertical axis ranges from negative twenty to forty centimetres of water. The bottom graph plots airflow on the vertical axis labelled airflow litres per minute, against time on the horizontal axis. The vertical axis ranges from zero to eighty litres per minute. Both graphs share a horizontal time scale marked from zero to twelve seconds. The top left corner includes a label that reads plot one breath synchronised.

FIG. 39.8 The pressure-time and flow-time waveforms of a patient with severe UAO due to an occlusion in the ETT. Note the near-horizontal expiratory flow after the initial ventilator circuit exhalation.

UAO results in high inspiratory pressure and an increased peak-to-plateau gradient in VCV, prolonged expiratory flow and auto-PEEP. However, those waveform changes alone, during the inspiratory phase of ventilation, do **not** discriminate between upper and lower airway obstruction.

The main differentiating waveform abnormality between UAO and LAO is the shape of the expiratory flow curve (Fig. 39.9). As discussed earlier, in LAO a deep concave curve is present as a result of increasing expiratory flow resistance during expiration and variable closure of small airways. In UAO the resistance is relatively fixed and so the result is a linear (or nearly linear) expiratory flow curve (Fig. 39.10).



The set of three graphs depicts airway pressure curves under different conditions. The first graph on the left is labelled normal with a description of a triangular shallow curve and positive end expiratory volume one to tidal volume at ninety percent. The second graph in the middle is labelled lower airway obstruction with a description of a deep concave curve, less than eighty percent in the first second resistance as lung volume increases, plus constant airway closure. The third graph on the right is labelled upper airway obstruction with a description of shallow linear slope, less than eighty percent in the first second of resistance.

FIG. 39.9 Discrimination between normal, lower airway obstruction and upper airway obstruction on flow-time waveforms by the expiratory flow waveform shape.

The medical monitor screen contains respiratory data of a patient on September twenty sixth two thousand five at nineteen twenty two. The top section lists numerical values for various respiratory parameters. From left to right, these values include peak pressure at twenty three centimetres of water, mean pressure at eighteen centimetres of water, positive end expiratory pressure at one point two three, inspiratory to expiratory ratio at twenty one, tidal volume at seven hundred twenty three milliliters, and total frequency at eleven point five breaths per minute. Below these numbers, two graphs plot waveforms over time. The upper graph represents airway pressure, while the lower graph represents airflow. The left side of the graphs includes a scale with numerical markers for measurement. At the bottom of the screen, labels read bilevel pressure control, pressure support, and patient trigger with a weight of eighty kilograms.

FIG. 39.10 PCV with upper airflow obstruction. Note near linear expiratory flow waveform. Note the large difference in inspired V_t between a triggered inspiration with patient effort and a controlled inspiration without patient effort.

Causes of UAO

1. Inline suction catheter is left partially in the ETT (a very common cause)
2. ETT kinked at the external fixation device
3. ETT rotated after insertion with kink inside the mouth
4. ETT too small (e.g. <7 mm ID)
5. Patient biting the ETT
6. Sputum accumulation inside the ETT. This is almost always in the distal third of the ETT, and most commonly occurs in patients with tenacious sputum or blood in their airways. The suction catheter can pass through this without a noticeable problem. On ETT removal, the remaining lumen is the size of the suction catheter running through the sputum occluded section.
7. Sputum or other material in the large airways beyond the ETT.
8. ETT in the right main bronchus. In this situation, the entire V_t is going into one lung and is delivered via a much smaller airway. This simulates large airway obstruction on the expiratory flow waveform.
9. Abnormal rotation of a tracheostomy tube. This problem can occur when an adjustable flange tracheostomy is used. This style of tracheostomy tube allows a variable insertion distance from the flange but also allows for rotation of the tracheostomy tube if not secured correctly. Occasionally this rotation can lead to the tracheostomy tube being directed to the side wall of the trachea obstructing flow.
10. Other airway pathology resulting in narrowed large airways (e.g. intraluminal tumour or extrinsic compression)

Recognition of a UAO should lead to a systematic troubleshooting pathway.

1. Carefully check the ventilator circuit and the ETT, including inside the mouth.
2. Check the chest x-ray, look for abnormal position of the ETT or tracheostomy.
3. Remove and inspect the inner cannula of the tracheostomy (if present).
4. Perform a bronchoscopy to check the ETT lumen or consider changing the ETT.
5. Clear secretions or foreign bodies from the patient's airways.
6. If there is a mid-tracheal lesion or extrinsic compression, consider trying to bypass the problem by inserting the ETT further.

C. M-waves

M-wave is a common way to describe abnormal biphasic inspiratory flow patterns usually as a result of a patient's inspiratory effort.

It may be seen in the pressure-time curve during VCV or in the flow-time curve during PCV ventilation. Most M-waves are due to unmet flow demands during inspiration in VCV or biphasic flow demands in PCV. M-waves fall into three common patterns.

1. Flow Starvation

Flow starvation is seen as a dip in the middle of a triggered VCV breath on the pressure-time waveform (Fig. 39.11). It is due to ventilator's inspiratory flow not meeting the patient's flow requirement in the middle of the breath, hence the term flow starvation. If the V_t delivered is adequate for the patient, the patient's effort will relax before the end of the breath. The result is an end-inspiratory pressure that approximates what would have been reached during a controlled breath. If a spontaneous breath occurs, it can be seen that the flow pattern in the spontaneous breath does not match that of the ventilator breath, usually, a much higher flow is seen in the middle of the breath compared to the flow delivered with a decelerating flow pattern.

The medical monitor screen contains respiratory data of a patient on October sixteenth two thousand ten at fourteen fifty six. The top section lists numerical values for various respiratory parameters. From left to right, these values include peak pressure at eleven centimetres of water, mean pressure at three centimetres of water, positive end expiratory pressure at one point seven, inspiratory to expiratory ratio at one point seven zero, tidal volume at zero millilitres and total frequency at one point five nine breaths per minute. Below these numbers, two graphs plot waveforms over time. The upper graph represents airway pressure, while the lower graph represents airflow. The left side of the graphs includes a scale with numerical markers for measurement. At the bottom of the screen several buttons with icons appear for control options on the monitor.

FIG. 39.11 Flow starvation: note all breaths are triggered by the patient. Also, note the difference in inspiratory flow pattern between

the assisted (*green*) and spontaneous (*red*) breaths. (A degree of expiratory airflow obstruction is also present in this example).

Increasing the inspiratory flow rate or changing the inspiratory flow pattern (e.g. to a square wave or parabolic wave) usually does not help as the flow pattern still does not suit the patient's inspiratory effort. Changing to a pressure-control or pressure-supported mode of ventilation usually resolves this problem. Alternatively, increasing minute ventilation (e.g. increasing resp rate) may decrease the respiratory drive of the patient, thereby eliminating the patients effort and allowing controlled breaths.

2. Volume Starvation

This also usually occurs during a triggered VCV breath. Similar to flow starvation, a dip in the middle of the breath is seen in the pressure-time waveform (Fig 39.12). However, instead of relaxing toward the end of the inspiratory time period, the patient's effort continues to and sometimes beyond, the end of the inspiratory cycle. The end-inspiratory pressure is lower than that which would have occurred in a controlled breath, and the patient's V_t exceeds that set by the ventilator. If the patient's effort continues past the refractory period of the ventilator, a spontaneous breath can be 'stacked' on top of the previous breath before expiration can occur (Fig 39.13). Flow starvation is always part of a volume starvation pattern but is not listed as a separate problem. Increasing the V_t does not usually help as the flow pattern does not usually suit the patient and a flow starvation pattern is seen. Again, changing to pressure control or pressure support ventilation will resolve the volume starvation problem, but it necessarily will result in a larger tidal volume.

The medical monitor screen contains respiratory data of a patient on April sixteenth two thousand nine at seventeen twenty eight. The top section lists numerical values for various respiratory parameters. From left to right, these values include peak pressure at six point four centimetres of water, mean pressure at five centimetres of water, positive end expiratory pressure at one point seven seven, inspiratory to expiratory ratio at eight point seven, tidal volume at five hundred seventeen millilitres and total frequency at three point zero five breaths per minute. Below these numbers, two graphs plot waveforms over time. The upper graph represents airway pressure, while the lower graph represents airflow. The left side of the graphs includes a scale with numerical markers for measurement. At the bottom of the screen several buttons with icons appear for control options on the monitor.

FIG. 39.13 Volume starvation. Patient effort continues beyond the refractory period at the end of the inspiratory cycle and a spontaneous breath is 'stacked' on top of the assisted breath.

It then has to be decided if the volume is too large for the patient with a risk of patient self-induced lung injury (P-SILI).

There are several ways of determining if V_t risks P-SILI

1. Patients who already have lung injury are at increased risk and should have more V_t restraint.
2. If there are any controlled breaths, P_{plat} can be measured and compliance and driving pressure (P_{dr}) can be calculated. Assuming linear compliance, the P_{dr} and end-inspiratory P_{alv} can be calculated from the tidal volumes taken by the patient. If these exceed safe limits, then the patient is at risk of P-SILI. P_{dr} <14 cm H_2O has been reported as a safe limit. [2]
3. If an oesophageal balloon is present or can be inserted, this will allow measurement of the trans-pulmonary driving pressure (P_{tpd}) and to see if it exceeds a safe limit (P_{tpd} <10 cm H_2O). [3]

There are several ways of addressing the P-SILI risk

1. Increase the set ventilation rate to reduce the $PaCO_2$ and increase the pH.
   This is done to try to reduce the patient's respiratory drive and facilitate controlled ventilation with a smaller V_t .
2. If V_t remains too big and there is a risk of P-SILI or P-SILI occurring, try increasing sedation to achieve controlled ventilation.
3. If this does not work and P-SILI is occurring, consider using an NMBA for 48 hours and see if lung function improves.

3. Reverse Triggering

Reverse triggering is an unusual phenomenon but can be found not infrequently when looked for. It is an M-wave with a patient effort occurring during the inspiratory cycle (Fig. 39.14). This effort may be finished before the end of inspiration or may continue after inspiration. The effort commonly results in a larger V_t than was set on the ventilator.

The medical monitor screen contains respiratory data of a patient on February twenty ninth two thousand sixteen at one twenty. The top section lists numerical values for various respiratory parameters. From left to right, these values include peak pressure at fourteen centimetres of water, mean pressure at eleven centimetres of water, positive end expiratory pressure at one point two three, inspiratory to expiratory ratio at twenty, tidal volume at five hundred twenty six millilitres and total frequency at ten point zero six breaths per minute. Below these numbers two graphs plot waveforms over time. The upper graph represents airway pressure, while the lower graph represents airflow. The left side of the graphs includes a scale with numerical markers for measurement. At the bottom of the screen, labels read synchronised intermittent mandatory ventilation volume control, pressure support and patient trigger with a weight of eighty five kilograms. Additional settings include tidal volume at five hundred milliliters, respiratory rate at twenty breaths per minute, positive end expiratory pressure at five centimetres of water, oxygen concentration at forty five percent and inspiratory time at one point zero seconds. Several buttons with icons appear for control options on the monitor.

FIG. 39.14 Reverse triggering. Note **none** of these breaths are triggered but an apparent patient effort occurs after ventilator initiation of each respiratory cycle.

The M-wave mimics the appearance of flow or volume starvation; however, unlike these waveforms that occur during a patient trigger breath, reverse triggering always occurs in a control-initiated breath. Reverse triggering usually occurs during every ventilator breath, but it may occur in a fraction of the breaths (e.g. every second breath). It almost always occurs in a sedated patient and may occur at the commencement of mechanical ventilation or during the waning phase in patients with lung injury. This may result in larger V_t's and increase the degree of lung injury.

It is a result of ventilator inspiration triggering the patient to make an inspiratory effort (hence termed ‘reverse triggering’). It is the opposite of the Herring-Breuer reflex and was first described by Head in 1889, 4 but has only crept into ICU understanding in the last decade.

The diagnosis can be confirmed by turning the ventilator rate up or down, the M-wave frequency will track the ventilator rate. Switching the ventilator mode to spontaneous will result in apnoea as these are not patient-triggered efforts. Increasing the level of sedation usually does not work unless high levels of sedation are used. Decreasing the level of sedation is the best solution and will usually resolve the problem as the sedation wears off. In the meantime, the set V_t should be decreased to reduce excessive V_t. The abnormal pattern just has to be tolerated until it resolves.

D. Self-cycling

Self-cycling occurs as a result of non-inspiratory efforts triggering the ventilator and can result in very rapid respiratory rates, making the patient look distressed and cause hypocapnic alkalosis (Fig. 39.15).

Several buttons with icons appear for control options on the monitor.

FIG. 39.15 Pressure-time and flow-time waveforms in self-cycling. Note that active expiratory flow variation can be seen when the expiratory period is long enough to allow this.

Self-cycling usually occurs in flow-triggered ventilation, and if the trigger is changed to pressure triggering the self-cycling will commonly resolve. There are a number of causes of this problem and these should be actively looked for and managed.

1. Circuit air leak – the ventilator assumes the patient is attempting to breathe due to a drop in bias flow resulting in the triggering of inspiration.
2. Hyperactive cardiac pulsation.
3. Shivering, rigour or seizure.
4. Water in the inspiratory or expiratory limb of the circuit.
5. Temporary pacing wires triggering the diaphragm.

Once the causative problem is found, the appropriate steps need to be taken to resolve it.

E. Missed inspiratory effort

This is seen as an upward deflection in the waveform during a normal expiratory flow pattern (Fig. 39.16). This results from a patient's inspiratory effort during the expiratory cycle, which reduces the expiratory flow, but it is not sufficient to trigger a ventilator breath. [5] This may be due to significant weakness, but is often the result of a V_t that is too large leading to a degree of gas trapping. Reducing the V_t will often resolve this problem. During pressure-supported breaths, V_t reduction can be achieved by reducing the pressure support or by shortening the inspiratory cycle by increasing E-sens (the percentage of peak inspiratory flow at which the ventilator terminates inspiratory pressure support e.g. from 25% to 40%). The result will allow these extra inspiratory efforts to trigger a ventilator breath. Inevitably the respiratory rate will increase, and care must be taken to ensure this problem is not mistakenly labelled a failure of pressure support weaning. Vigilance is required to identify missed inspiratory efforts prior to reducing the pressure support.

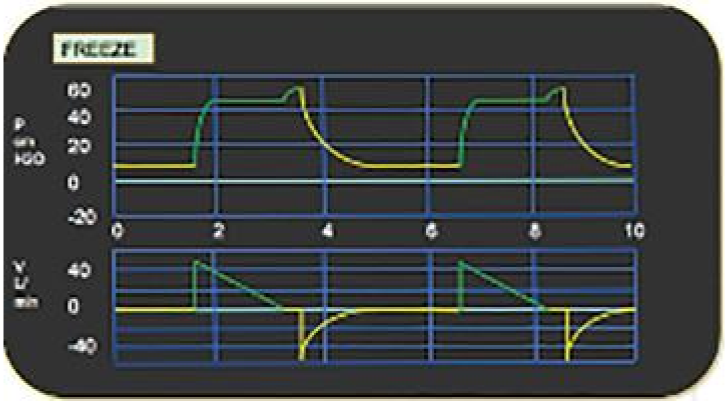
The medical monitor screen contains respiratory data of a patient on April eighth two thousand sixteen at seventeen zero eight. The top section lists numerical values for various respiratory parameters. From left to right, these values include peak pressure at nine point six centimetres of water, mean pressure at five point seven centimetres of water, positive end expiratory pressure at one point nine, inspiratory to expiratory ratio at twenty three, tidal volume at four hundred forty two millilitres and total frequency at ten point one breaths per minute. Below these numbers, two graphs plot waveforms over time. The upper graph represents airway pressure, while the lower graph represents airflow. The left side of the graphs includes a scale with numerical markers for measurement. At the bottom of the screen, labels read spontaneous volume control pressure support and volume trigger with a weight of seventy kilograms. Additional settings include tidal volume at five hundred milliliters, respiratory rate at twelve breaths per minute, positive end expiratory pressure at three centimetres of water, oxygen concentration at thirty five percent and inspiratory time at two point five seconds. Several buttons with icons appear for control options on the monitor.

FIG. 39.16 Missed inspiratory efforts. Note the upward deflection of the flow-time curve that is insufficient to trigger breaths.

F. Premature Exhalation

Premature exhalation can be identified as a stepwise increase in pressure toward the end of inspiration on the pressure-time graph during triggered VCV (Fig. 39.17). It usually occurs when the inspiratory time is too long for the patient and the patient commences an active expiratory effort instead of the usual passive expiration.



The medical monitor screen contains two graphs of respiratory data in a freeze mode. The top graph plots airway pressure on the vertical axis, labelled airway pressure centimetres of water, against time on the horizontal axis. The vertical axis ranges from negative twenty to sixty centimetres of water. The bottom graph plots airflow on the vertical axis, labelled airflow litres per minute, against time on the horizontal axis. The vertical axis ranges from negative forty to forty litres per minute. Both graphs share a horizontal time scale marked from zero to ten seconds. The top left corner includes a label that reads freeze which indicates that the data capture pauses for review.

FIG. 39.17 Premature exhalation in simulated pressure-time and flow-time waveforms. Note the increase of the pressure-time curve toward the end of inspiration.

Once identified, management is simply to reduce the inspiratory time either directly (i-time, or I:E ratio) or by increasing the peak flow.

G. Complex Problems

When caring for complex ICU patients, you may identify patients with more than one waveform abnormality. For example M-Waves sometimes coexist with airflow obstruction (Fig. 39.11). This may be a coincidence, or it may be that airflow obstruction predisposes to abnormal inspiratory efforts. It is important to identify both problems and to troubleshoot them.

Significant amounts of information can be gleaned by interrogating ventilator waveforms and all clinicians should make it routine practice. Tailoring ventilator settings to patient requirements is an important component of daily ICU care. Sedation and paralysis to make the patient ‘fit’ the ventilator settings should be a last resort.

Chest imaging and ultrasound in the ICU

Bhavin Rawal and Ubbo F. Wiersema

Chest Imaging

Chest radiography is the principal imaging modality for the investigation of intensive care patients. [1] Lung ultrasound plays a complementary role to the radiograph in selected patients. Computed tomography (CT) is indicated in specific situations to provide additional diagnostic information.

Chest Radiography

A chest radiograph is indicated for the initial evaluation of critically ill or injured patients, after the placement of invasive devices, or whenever there is a significant deterioration in the clinical status of the patient. Unlike the erect posteroanterior and lateral chest radiographs performed on ambulant patients inspiring to total lung capacity, the portable intensive care radiograph has several disadvantages:

- Relative anatomical distortion due to anteroposterior projection
- Magnification due to shorter focus-film distance
- Movement blurring because of long exposure times due to limited X-ray output
- Inability to position the patient erect
- Inability of the patient to inspire total lung capacity (spontaneously or mechanically ventilated)

Normal Radiographic Anatomy

The Mediastinum, Hilar Structures and Central Airways

The various structures of the mediastinum are superimposed on each other so cannot be separately identified. Key points include:

- Only the outline of the mediastinum and the air-containing trachea and bronchi (and sometimes oesophagus) are clearly seen on a normal chest radiograph.
- The right superior mediastinal border is formed by the right brachiocephalic vein and superior vena cava (SVC) and becomes less distinct as it reaches the thoracic inlet. The right side of the superior mediastinum can appear considerably widened in patients with an abundance of mediastinal fat.
- The left mediastinal border above the aortic arch is formed by the summation of the left carotid and subclavian arteries, together with the left brachiocephalic and jugular veins.
- The trachea and main bronchi should be visible through the upper and middle mediastinum, with the trachea in the midline. Displacement of the trachea may be caused by a dilated aortic arch.
- In approximately 60% of normal subjects the right wall of the trachea (the right paratracheal stripe) can be identified as a line of uniform thickness (less than 4 mm in width); when it is visible it excludes the presence of an adjacent space-occupying lesion, such as lymphadenopathy.
- The carinal angle is usually less than 80 degrees. Splaying of the carina is an insensitive sign of subcarinal disease, either in the form of massive subcarinal lymphadenopathy or a markedly enlarged left atrium.
- The origins of the lobar bronchi, where they are projected over the mediastinum, can usually be identified, but the segmental bronchi within the lungs are not generally visible.
- The left cardiac border comprises the left atrial appendage, which merges inferiorly with the left ventricle. The silhouette of the heart should always be sharply outlined. Any blurring of the border is

due to the loss of an immediately adjacent aerated lung, usually by collapse or consolidation.

- The density of the heart shadow to the left and right of the vertebral column should be identical, and any difference indicates pathology, such as lower lobe consolidation or a mass.
- Normal hilar shadows on a chest radiograph represent the summation of the pulmonary arteries and veins.
- The hila are approximately the same size; the left hilum normally lies 0.5 cm to 1.5 cm above the level of the right hilum. The size and shape of the hila show remarkable variation in normal individuals, making subtle abnormalities difficult to identify.

The Pulmonary Fissures, Vessels and Bronchi

- The four layers of pleura in front and behind the mediastinum, that separate the two lungs, may be visible as nearly vertical stripes.
- The major (oblique) fissures are not visible on frontal radiographs; the minor (horizontal) fissure of the right lung is visible in more than half of normal chest radiographs.
- All of the branching structures seen within normal lungs represent pulmonary arteries or veins. It is often impossible to distinguish arteries from veins in the lung periphery.
- In the erect position, there is a gradual increase in the diameter of the vessels, at equidistant points from the hilum, travelling from lung apex to base; this gravity-dependent effect disappears if the patient is supine or in cardiac failure.

The Diaphragm

- The interface between the aerated lung and diaphragm is sharp; any blurring usually represents pleural disease such as pleural thickening or effusion.
- The highest point of the dome of each diaphragm is usually medial to the midclavicular line.
- The right dome is higher than the left by up to 2 cm in the erect position unless the left dome is elevated by air in the stomach (

Fig. 40.1).

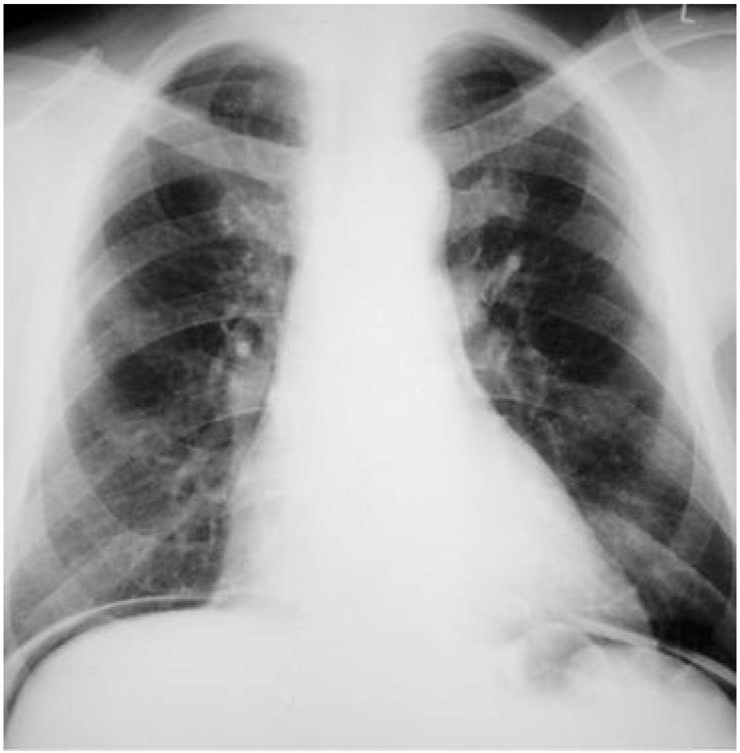

FIG. 40.1 Erect chest radiograph of a patient with a pneumoperitoneum demonstrating the normal thickness and position of the hemidiaphragms. The right lies slightly higher than the left.

The Positioning of Tubes and Lines

Endotracheal Tubes

Flexion or extension of the neck may make the distal tip of the endotracheal tube move by as much as 2.5 cm up or down the trachea, respectively. Thus with the neck in a neutral position, the tip of the endotracheal tube should lie about 4 to 5 cm above the carina (Fig. 40.2). A tube that is inserted too deeply into the trachea usually passes into the right main bronchus, with the risk of under-ventilation and collapse of the left lung.

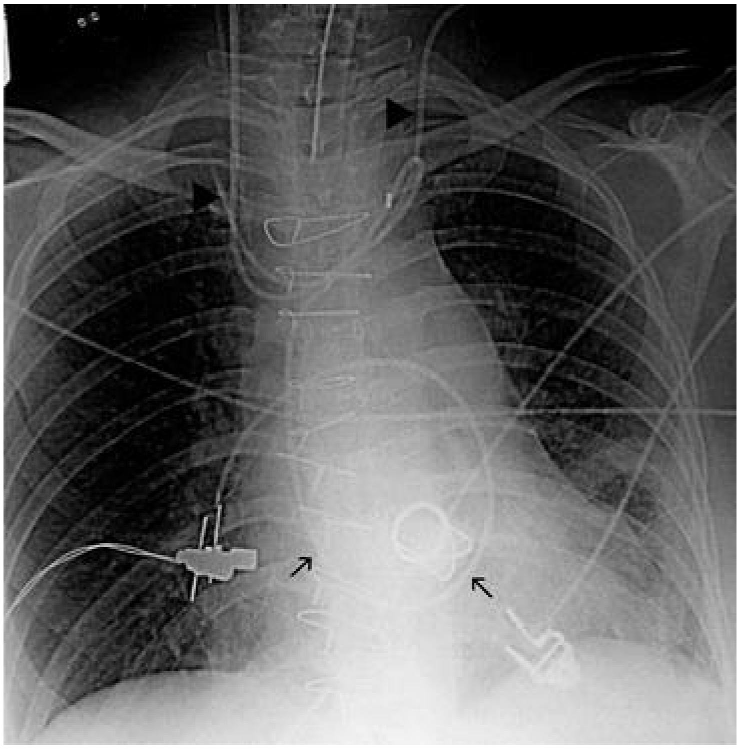

FIG. 40.2 Intensive care unit patient with multiple tubes and catheters in place. The endotracheal tube tip position is satisfactory, and there are sternotomy wires, an intra-aortic balloon pump (radiopaque tip in the proximal descending aorta) and a prosthetic heart valve. The central venous catheter inserted into the left internal jugular vein passes into the right internal jugular vein. The pulmonary artery catheter, inserted via the right internal jugular vein, loops into the left brachiocephalic vein, before taking a satisfactory course through the cardiac chambers *(black arrows)* .

Tracheostomy Tubes

The tracheostomy tube should lie in the midline of the trachea. Complications of tracheostomy insertion include pneumothorax, pneumomediastinum and subcutaneous emphysema.

NasOgastric Tubes

The distal tip of a nasoenteric tube should reach the stomach, below the diaphragm (Fig. 40.3). The course of the tube through the mediastinum may reveal abnormal oesophageal displacement by mediastinal structures. Viewing the radiograph with an inverted greyscale can sometimes help to visualise the tube.

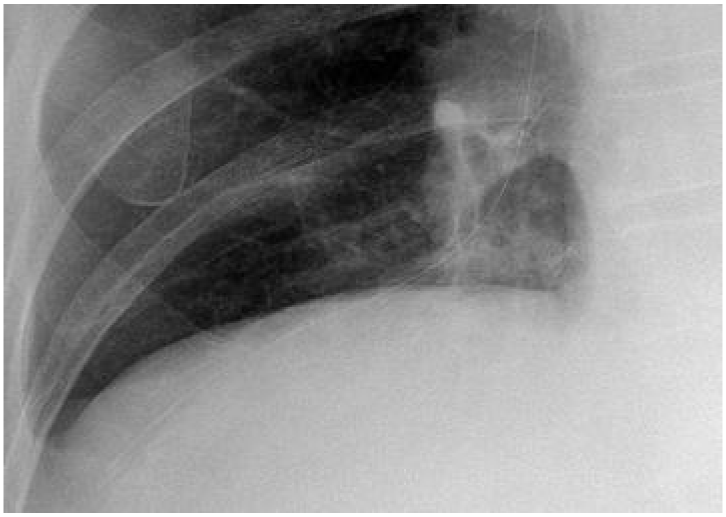

FIG. 40.3 Misplaced nasogastric tube.

Central Venous Catheters

The distal tip of a central venous catheter should lie beyond the most proximal venous valves of the central veins (which are located 2 to 2.5 cm from the SVC in the left and right brachiocephalic veins), and ideally in the SVC. The catheter tip should not abut the vessel wall at an obtuse angle. Catheter insertion may be complicated by pneumothorax from inadvertent lung puncture or rarely mediastinal haemorrhage or haemothorax from subclavian vein perforation. The catheter may also become coiled, knotted or fractured.

Pulmonary Artery Catheter

Ideally, the distal tip of a pulmonary artery catheter should lie in the right or left pulmonary artery, less than 5 to 8 cm beyond the bifurcation of the main pulmonary artery (Fig. 40.2). If the tip lies any deeper into the pulmonary artery the tip may wedge spontaneously with risk of pulmonary infarction, or balloon inflation may cause pulmonary artery rupture and haemorrhage.

Intra-Aortic Balloon Pump

The balloon catheter has a radiopaque tip, which may be the only part of the catheter visible on the radiograph. The tip should lie just distal to the origin of the left subclavian artery (Figs. 40.2 and 40.4). A tip that is placed too high risks perforation of the aortic arch. If the tip is too low the catheter may occlude branches of the abdominal aorta.

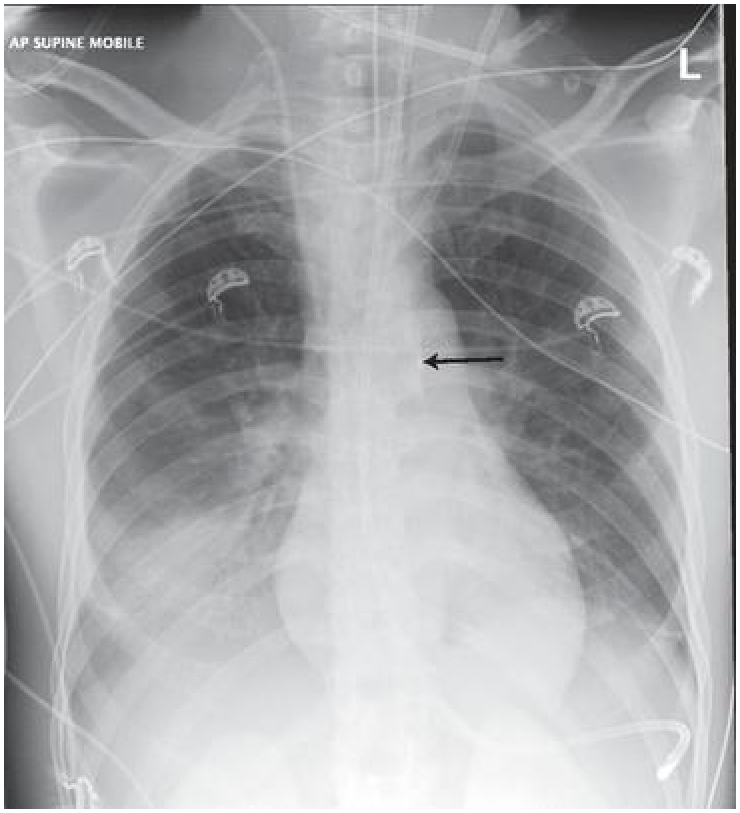

FIG. 40.4 Intra-aortic balloon pump. The tip *(arrow)* is seen appropriately positioned in the proximal descending aorta. The patient suffered septic cardiomyopathy due to multilobar pneumococcal pneumonia.

Pacemakers

Temporary epicardial pacing wires placed during cardiac surgery may be seen as thin, almost hair-like metallic opacities overlying the heart. The tip of a temporary transvenous right ventricular pacing wire should lie at the apex of the right ventricle, to the left of the spine (Fig. 40.5). The chest radiograph may demonstrate displacement, or fracture of the pacing wire.

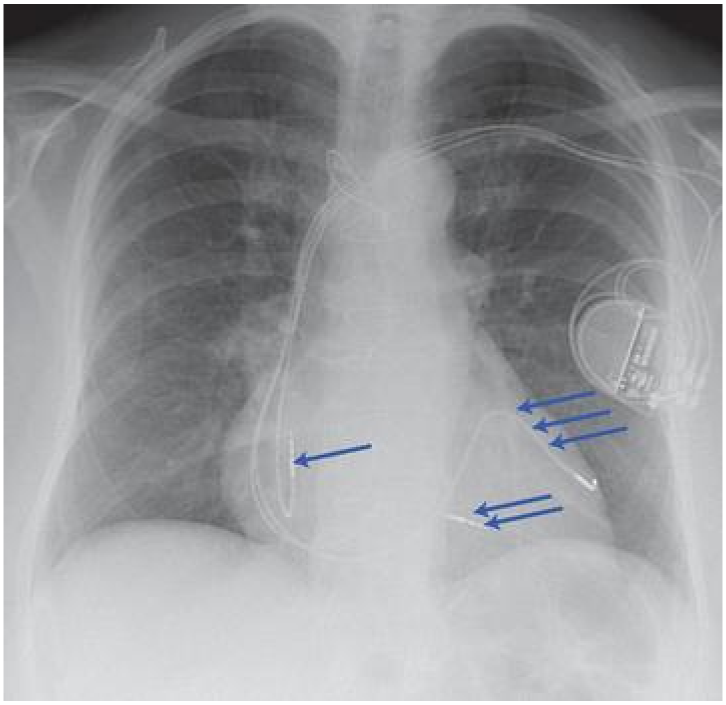

FIG. 40.5 Biventricular pacemaker. Note the right atrial lead *(arrow)* , right ventricular lead *(double arrows)* and coronary sinus lead *(triple arrows)* .

Extracorporeal Membrane Oxygenation (ECMO) Cannulae

For venovenous ECMO the usual configuration includes a femoral venous drainage cannula with the tip in the proximal inferior vena cava (IVC) and a right jugular return cannula with the tip in the proximal SVC.

For venoarterial ECMO the tip of the femoral venous drainage cannula is usually advanced into the right atrium (Fig. 40.6). It is important to ensure that the tip of the cannula does not abut the atrial wall, with a risk of atrial wall perforation. The femoral arterial return cannula is usually in the distal aorta and not visible on the chest radiograph. Cross-sectional imaging is often acquired at baseline to document cannula position.

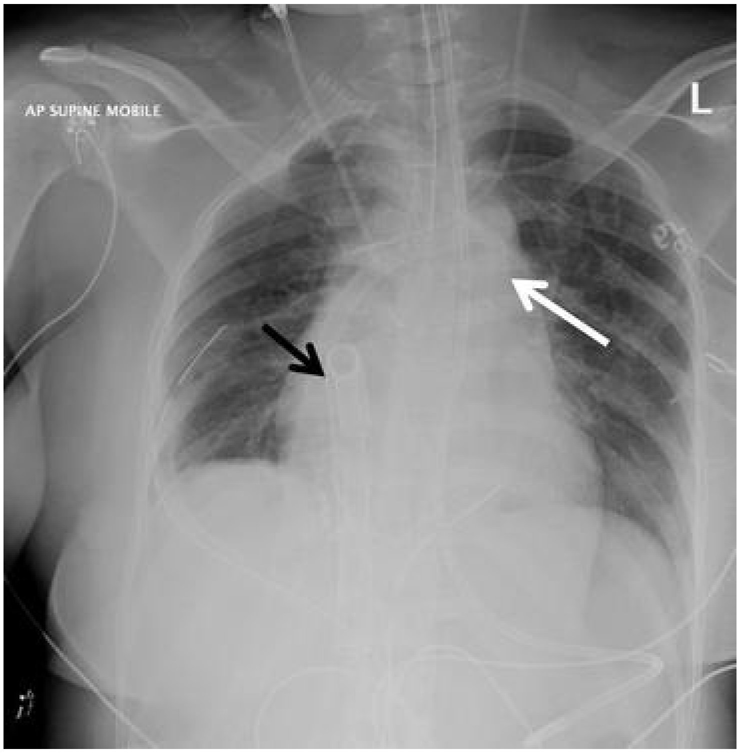

FIG. 40.6 Venoarterial-extracorporeal membrane oxygenation in a patient with massive pulmonary embolism. The drainage cannula is in the right atrium *(black arrow)* . The return cannula is in the proximal descending aorta *(white arrow)* .

Pleural Tubes

Most pleural tubes have a radiopaque line running along the length of the tube, with interruptions of the line where there are side holes. It is important to check that all the side holes lie within the thorax. If there is doubt about the tube position, a CT scan should be considered (Fig. 40.7).

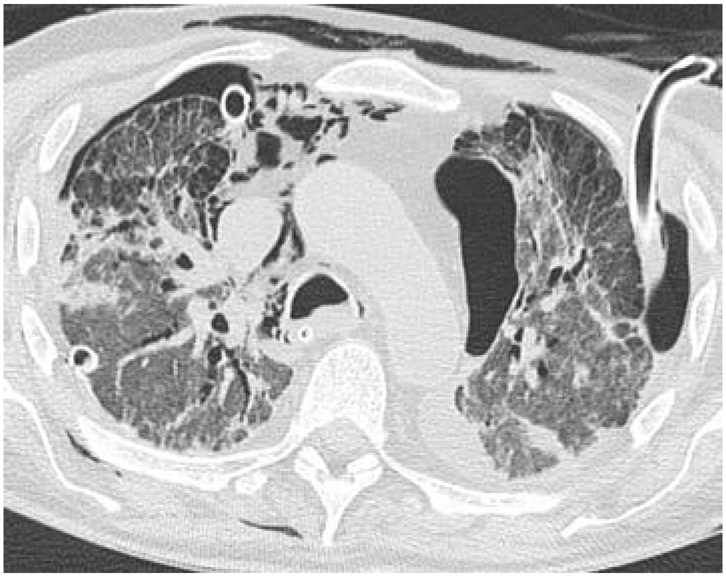

FIG. 40.7 Computed tomography scan demonstrating bilateral pneumothoraces in a patient with acute respiratory distress syndrome. Note is made of bilateral chest drains.

Radiographic Signs of Pathology

Consolidation

Consolidation refers to an area of airspace opacification due to alveolar and bronchiolar filling. Many causes of consolidation also cause some collapse with a slight loss of volume. The airspace filling may be due to pus (pneumonia), fluid (pulmonary oedema) or blood (pulmonary haemorrhage). Other radiographic signs should be sought, and clinical correlation made to determine the cause of airspace filling. Typical features of all forms of consolidation include (Fig. 40.8):

- Ill-defined margins
- Sharply demarcated fissures
- Loss of vascular markings
- Air bronchograms – the normally indistinguishable radiolucent bronchi stand out within the airspace opacification
- Silhouette sign – consolidation abutting a soft-tissue structure causes the silhouette of that structure to be lost

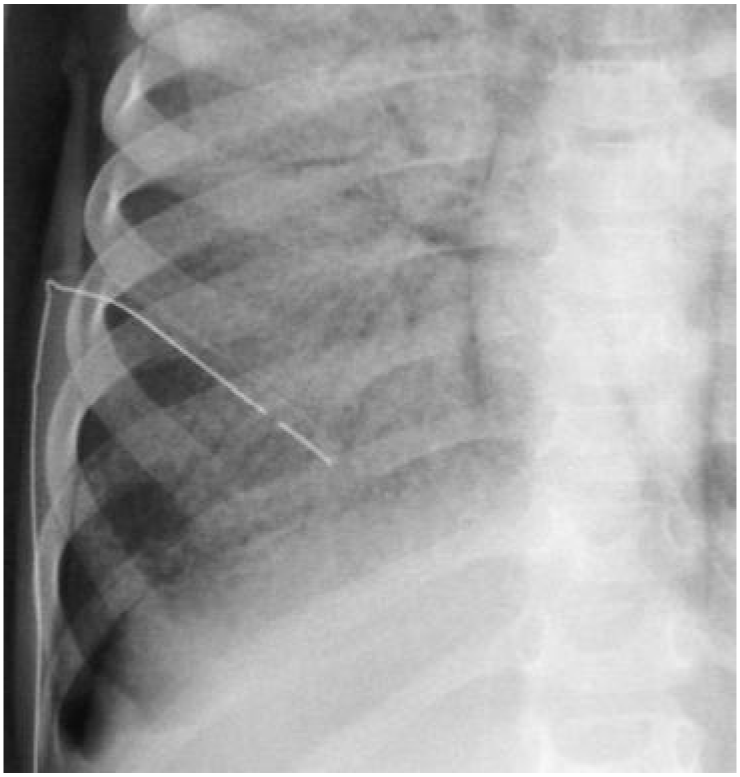

FIG. 40.8 Close-up view of an area of consolidation adjacent to the right heart border, which is obscured. Air bronchograms can be identified passing through this area. A chest tube is in situ.

Areas of consolidation that undergo necrosis with liquefaction due to infection or infarction may develop an air-fluid level within a cavity if there is either a gas-forming organism or communication with the bronchial tree.

Collapse

Partial or complete loss of volume of a lung or lobe is referred to as collapse or atelectasis. The different mechanisms of lung collapse include lung compression by pleural fluid or air, resorption collapse due to bronchial obstruction, adhesive collapse from lack of surfactant in ARDS and cicatrisation collapse from lung scarring and contraction. Radiographic signs of collapse include (Figs. 40.9 – 40.13):

- Displacement of interlobar fissures
- Crowding of vessels and bronchi
- Increased lung density from loss of aeration, or a silhouette sign

- Elevation of the hemidiaphragm and depression of the hilum with lower lobe collapse
- Ipsilateral displacement of the mediastinum and elevation of the hilum with upper lobe collapse
- Compensatory hyperinflation of the remaining lung, such that it appears darker (increased transradiancy)
- Crowding of ribs due to the diminished overall volume of the affected hemithorax

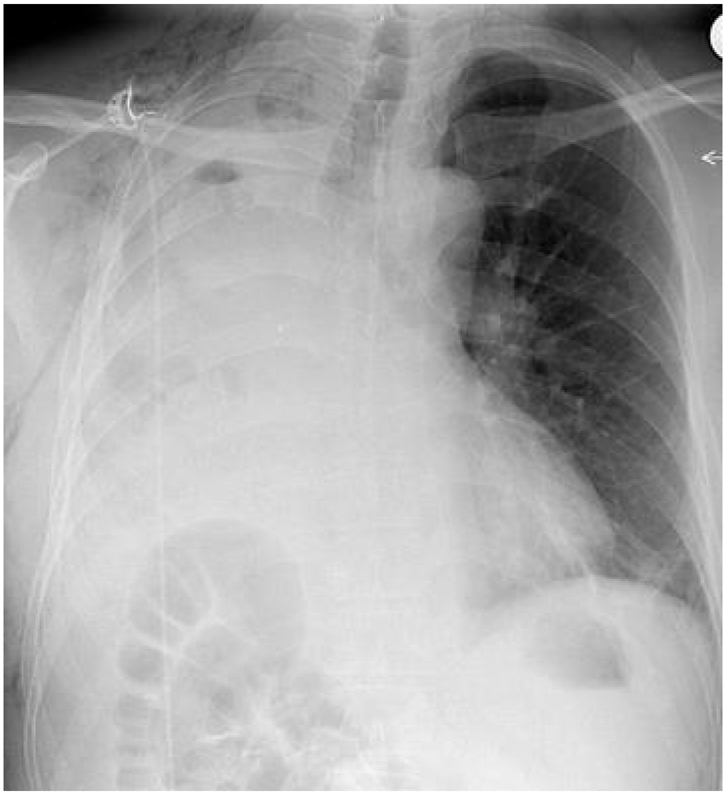

FIG. 40.9 Complete lung collapse. There was an obstructing tumour in the right main bronchus. The right hemithorax is opaque, the mediastinum has shifted and the trachea is deviated to the right.

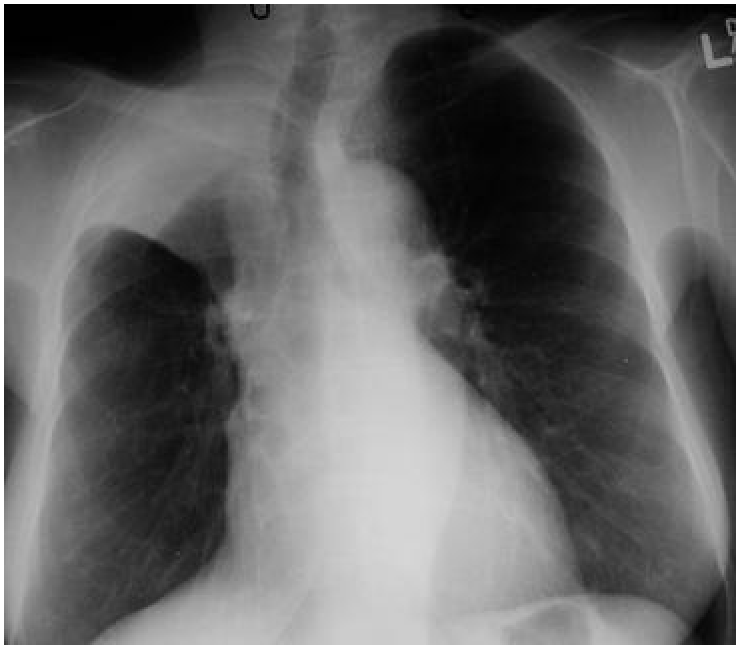

FIG. 40.10 Right upper lobe collapse. The horizontal fissure has become elevated and the right upper lobe has become a wedge-shaped density extending from the hilum to the right lung apex. There is evidence of volume loss with shift of the trachea to the right side.

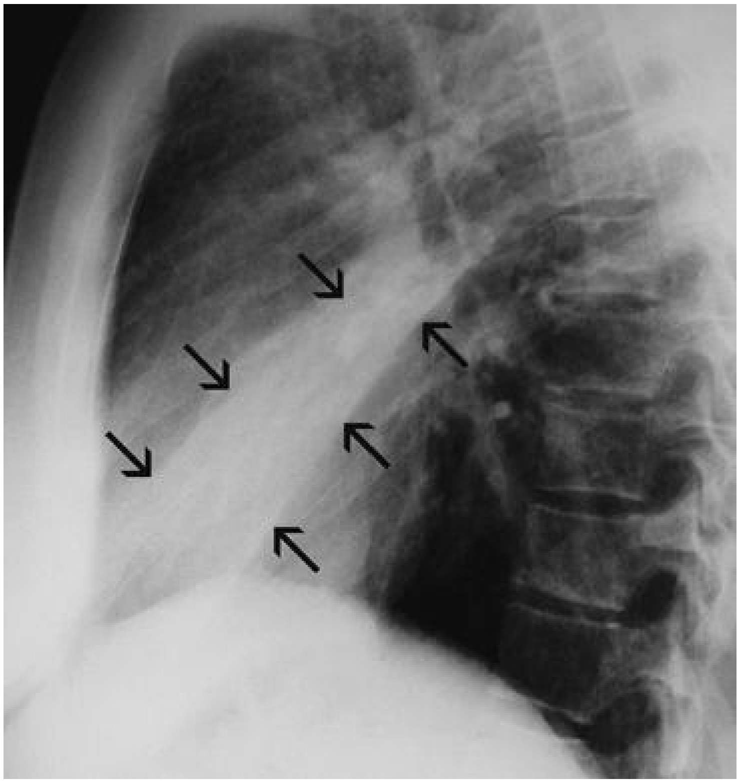

FIG. 40.11 Middle lobe collapse. The horizontal fissure is depressed and demarcates the collapsed middle lobe as a wedge-shaped density best demonstrated on the lateral *(arrows)* .

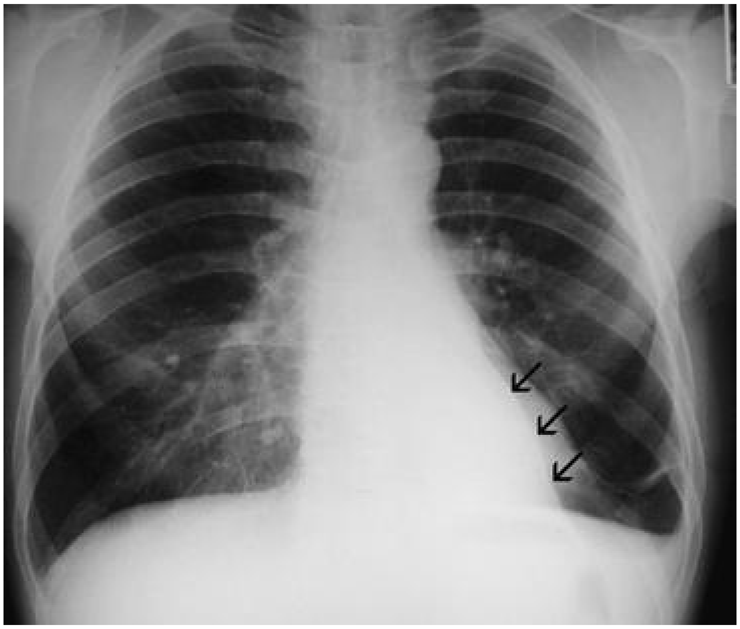

FIG. 40.12 Left lower lobe collapse. The left lower lobe has become a wedge-shaped density behind the heart, forming a double left heart border *(arrows)* . The left hilar vessel to the lower lobe has disappeared as a result of collapse.

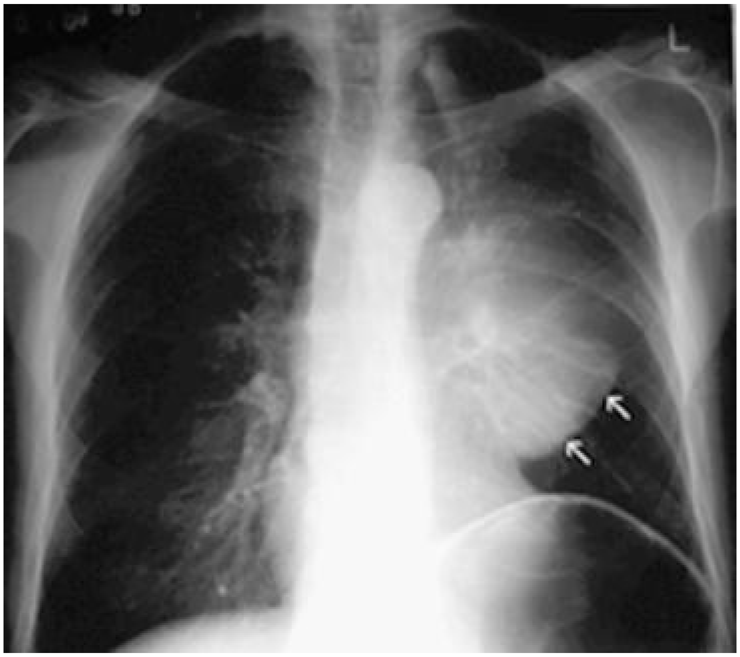

FIG. 40.13 Left upper lobe collapse. A hazy opacity extends from the hilum towards the left lung apex. It is sharply demarcated inferiorly and laterally *(white arrows)* owing to the presence of a large tumour at the left hilum, which is obstructing the left upper lobe bronchus. Note the signs of volume loss, particularly the elevation of the left hemidiaphragm.

Unilaterally increased transradiancy

Increased transradiancy is most commonly due to technical reasons such as patient rotation, poor beam centring or offset grids. This may be identified by comparison with the soft tissues around the shoulder girdle, particularly over the axilla.

Pathological causes include:

- Chest wall changes such as mastectomy or congenital absence of pectoralis muscle
- Reduced vascularity or regional pulmonary blood supply, such as with pulmonary embolism
- Lung hyperexpansion due to air trapping or asymmetric emphysema
- Relative increased transradiancy on one side may also appear to be present because of generalised increased radiopacity of the other

side, for example from posterior layering of a pleural effusion in a supine patient.

Mediastinal Abnormalities

Pneumomediastinum or mediastinal emphysema is the presence of air between the tissue planes of the mediastinum. Chest radiography may show vertical translucent streaks in the mediastinum, representing air separating the soft-tissue planes. The air may extend up into the neck, over the chest wall (causing subcutaneous emphysema) and over the diaphragm. The mediastinal pleura may be displaced laterally, which may be visible as a thin stripe alongside the mediastinum. Causes of pneumomediastinum include:

- Perforation of the oesophagus, pharynx or proximal tracheobronchial tree. Subsequent development of mediastinitis may manifest as mediastinal widening.
- Following cardiothoracic surgery. If this develops several days after surgery, sternal dehiscence and wound infection should be considered.
- Extension from a pneumothorax.
- Extension from pneumoperitoneum due to a perforated abdominal viscus or following laparoscopic surgery with peritoneal insufflation.

Mediastinal haemorrhage may occur from arterial or venous bleeding. The mediastinum appears widened and blood may be seen tracking over the lung apices (Fig. 40.14). It is imperative to identify a life-threatening cause such as aortic rupture.

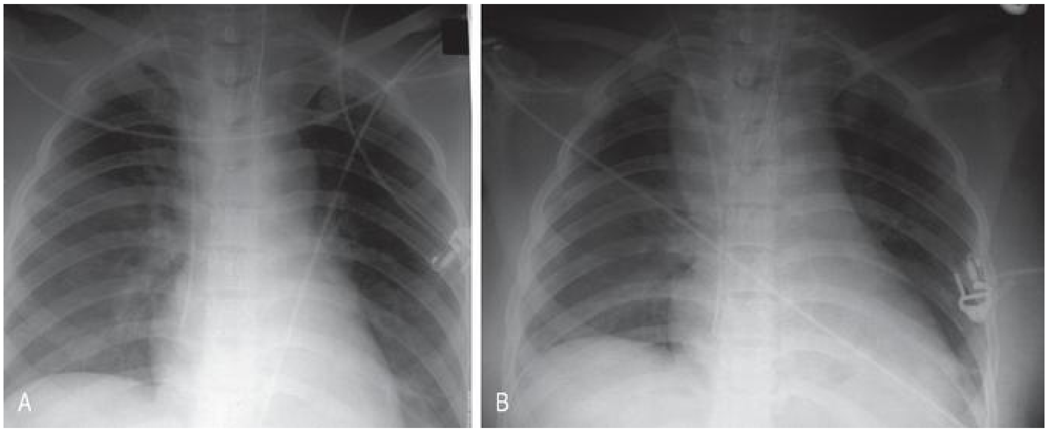

FIG. 40.14 Following cardiac surgery (A) the post-operative chest radiograph appears satisfactory. A few hours later (B) the mediastinum has widened considerably due to mediastinal haemorrhage.

Aortic dissection or aneurysmal dilatation may also cause widening of the mediastinal silhouette on chest radiography.

Pleural Effusion

A pleural effusion larger than about 250 mL becomes visible on an erect chest radiograph as blunting of the costophrenic angle. Larger effusions fill in the costophrenic angle with a concave upper edge, higher laterally than medially (Fig. 40.15). The lung base and diaphragmatic border become obscured by fluid and adjacent lung collapse. Fluid may track into the fissures. A massive effusion may cause complete opacification of the hemithorax and push the mediastinum towards the opposite side. In the supine patient, an effusion will redistribute into the paravertebral sulcus and appear as an even radiopacity of the hemithorax.

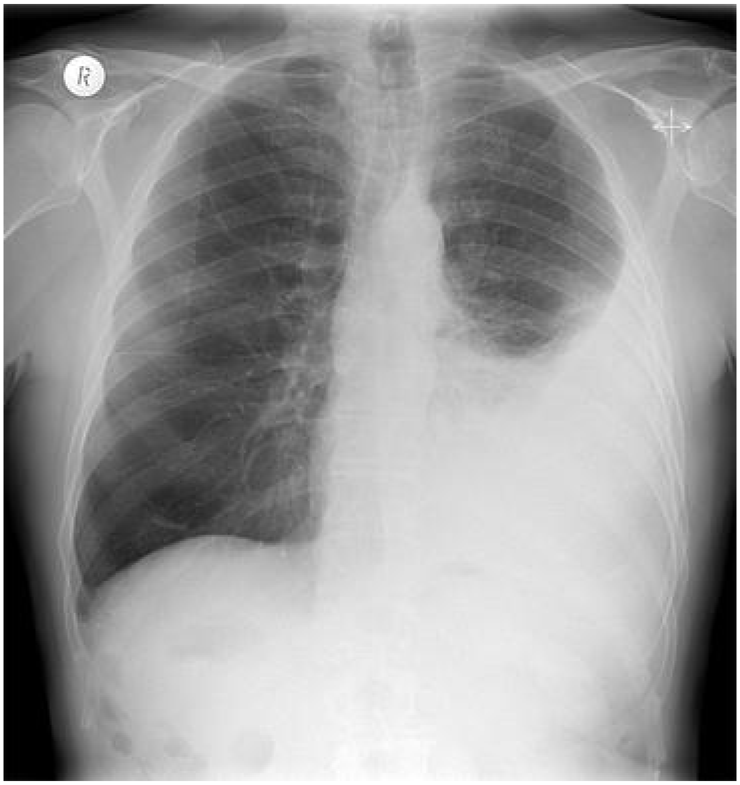

FIG. 40.15 Left pleural effusion. There is a typical configuration of the left upper border, a meniscus extending up the lateral chest wall.

Loculated fluid in the interlobar fissures is most frequently seen in heart failure.

Lamellar effusions are shallow collections between the lung surface and the visceral pleura, sometimes sparing the costophrenic angle and occur early in heart failure.

Subpulmonary effusions accumulate between the diaphragm and undersurface of a lung, mimicking elevation of the hemidiaphragm, altering the diaphragmatic contour so the apex moves more laterally than usual. When left-sided, there is increased distance between the gastric air bubble and lung base.

Differentiation between a simple effusion and a complicated parapneumonic effusion or empyema requires ultrasound or CT.

Pneumothorax

On an erect chest radiograph, a small pneumothorax may only be visible at the lung apex (Fig. 40.16). On the supine radiograph, air collects at the lung base, causing increased transradiancy towards the diaphragm and a deep sulcus sign. As the pneumothorax enlarges, the lung retracts towards the hilum and the sharp white line of the visceral pleura will be visible, separated from the chest wall by the radiolucent pleural space devoid of lung markings. This line should not be confused with a skin fold, which mostly occurs in supine or recumbent patients. The retracted lung usually remains aerated, but perfusion is reduced in proportion to ventilation, so the radiodensity of the lung remains relatively normal.

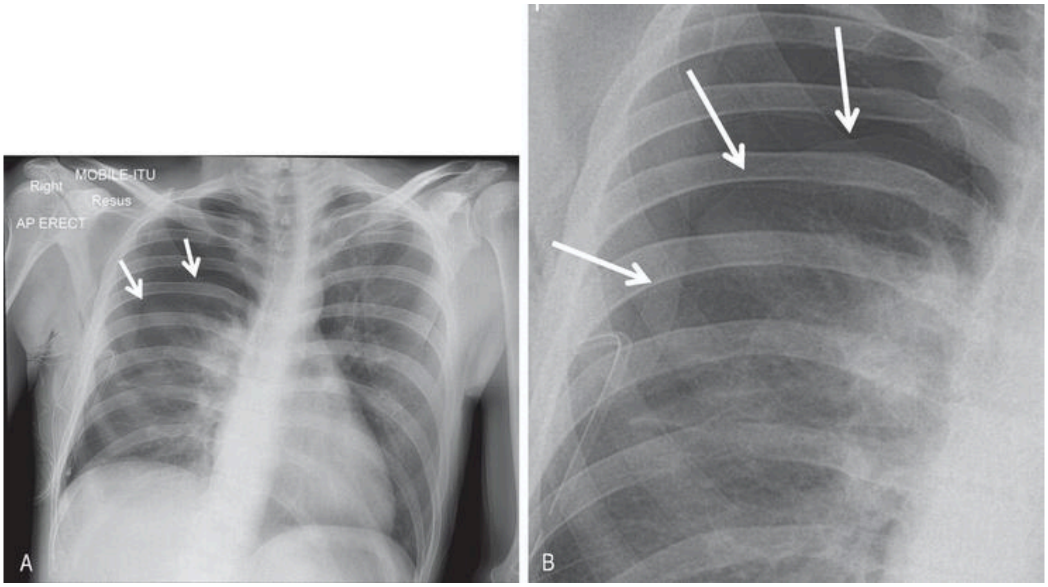

FIG. 40.16 Pneumothorax. (A) This patient, with underlying lung abnormality, has developed a pneumothorax. The fine white line that represents the visceral pleura delineates the edge of the lung *(arrows)* . (B) Close-up of the pleural line. Note how there are no vascular markings beyond this point.

Pneumothorax associated with pleural effusion (hydropneumothorax or haemopneumothorax) will show an air-fluid level on the erect radiograph (Fig. 40.17).

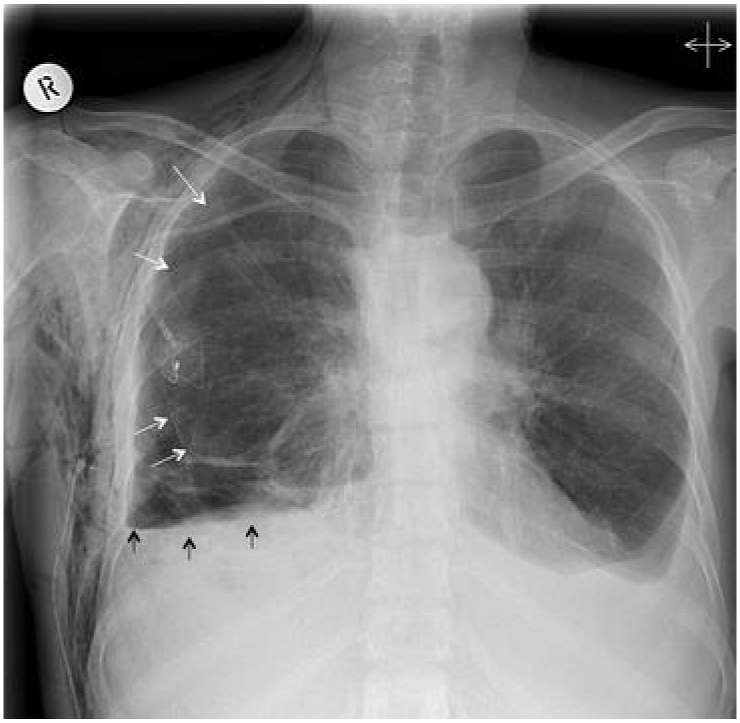

FIG. 40.17 Hydropneumothorax post biopsy. There is a thin white line due to pneumothorax *(white arrows)* associated with an air-fluid level *(black arrows)* due to fluid. The intercostal catheter has dislodged into the chest wall, causing surgical emphysema.

Tension pneumothorax occurs when a large pneumothorax causes the lung to be compressed against the mediastinum, with mediastinal shift towards the contralateral side and haemodynamic collapse.

Pulmonary Oedema

On the erect chest radiograph upper lobe pulmonary vessels will appear larger than lower lobe vessels if there is pulmonary venous hypertension. Interstitial oedema manifests as peribronchial and interlobular septal thickening. Alveolar oedema manifests as increased lung opacification, particularly affecting the perihilar regions in cardiogenic pulmonary oedema, but can be asymmetrical. Pleural effusion is commonly associated with pulmonary oedema.

Lung Ultrasound

Lung ultrasound complements the chest radiograph, particularly in the evaluation of pleural effusion, pneumothorax and pulmonary oedema.[2,3] Ultrasound is rapid, inexpensive and safe from ionising radiation, making it ideally suited to point-of-care use and repeated examination. Acute lung parenchymal pathology invariably abuts the pleura and can thus be detected by ultrasound. Diagnostic accuracy of ultrasound compares favourably with CT, and significantly exceeds clinical examination and plain radiography.

Limitations of ultrasound include difficulty imaging obese patients or those with dressings over the chest wall. Structures deep into the lung surface cannot be visualised.

The phased array, low-frequency (3–5 MHz) transthoracic echocardiography transducer provides good depth penetration and sufficient resolution for most chest ultrasound applications. A high-frequency linear array transducer (6–13 MHz) allows detailed pleural line analysis and is optimal for pneumothorax detection (e.g. after venous cannulation), but has limited other applicability.

Imaging in 2D is adequate for most examinations. M-mode is useful for lung sliding analysis.

Ultrasound examination of the lungs involves scanning bilaterally over four quadrants of the anterior chest wall (upper and lower zones laterally and medially), the upper and lower lateral chest wall (bounded by the anterior and posterior axillary lines), and upper, middle and lower zones of the posterior chest wall. For a complete study, each intercostal space, along multiple vertical lines, should be imaged. Only the dorsal lung segments behind the scapulae cannot be examined by ultrasound.

The examination sequence should commence with scanning of the lower lateral chest. Here identification of the diaphragm provides a useful landmark for further imaging. Subdiaphragmatic structures (liver, spleen and kidneys) may be identified to confirm the location of the diaphragm. Right-sided subdiaphragmatic structures are usually easier to visualise than left-sided structures. Diaphragmatic movement with tidal ventilation should be identified. The scanning depth should initially be set to 15–20 cm to evaluate basal lung pathology. The scanning depth can then be reduced to 10 cm (and the use of a higher-frequency transducer is considered) to facilitate artefact analysis and complete the examination over the whole chest wall.

For each region of interest, the transducer should be placed between the rib spaces and aligned with the longitudinal axis of the patient. The orientation marker on the transducer should face cephalad. By convention, the orientation marker is displayed on the upper left of the screen with abdominal ultrasound and displayed on the upper right of the screen with echocardiography. Choice of transducer and type of examination selected from the display menu will determine the default marker location on the screen.

Image Interpretation

For each region examined, image interpretation involves the identification of the pleural line between the ribs, artefact analysis, lung sliding analysis and evaluation of non-aerated pathology (e.g. pleural effusion and consolidation).

Extrapleural Landmarks

In 2D mode, with the transducer aligned with the longitudinal axis of the patient, the ribs above and below the pleural space cast a dark shadow that extends down to the full depth of the image on each side of the screen. Between the ribs, the pleural line forms a bright (hyperechoic) reference line for artefact and lung sliding analysis.

Artefact Analysis

Ultrasound waves cannot be transmitted through aerated tissue. Normal lung parenchyma is thus not visible beyond the visceral pleura. The pleural line is formed by the reflection of ultrasound waves at the interface between the pleura and lung parenchyma. All artefacts used for the analysis of lung pathology (except E lines) arise from the pleural line.

- *A-line artefacts* (Fig. 40.18): These are bright horizontal repetitions of the pleural line due to reverberation artefacts, and are a normal finding. [4] The vertical distance between two adjacent A lines is the same as the distance between the skin and the pleural line. Usually, only one or two A lines are visible, depending on image gain and depth settings.

- *B-line artefacts* (Fig. 40.19): These were previously known as *comet-tail artefacts* or *ultrasound lung comets* . They are defined as discrete vertical bright lines originating at the pleural line and fanning out to the bottom of the screen without fading.[4-6] B lines arise from reverberation artefacts generated at the interface of fluid-filled or fibrosed interlobular septa abutting the visceral pleura. The presence of multiple B lines, termed ‘ *B pattern* ’ , erases the A-line artefact. With greater loss of aeration, the B lines become more closely spaced, or confluent (*white-out*) (Fig. 40.20). Isolated B lines or short, ill-defined vertical artefacts are of uncertain significance (Table 40.1)
- *E-line artefacts* (Fig. 40.21): These have a very similar appearance to B lines but arise superficially to the pleural line. They occur with subcutaneous emphysema where pockets of air create an air–tissue interface that generates reverberation artefacts. The presence of E lines precludes further artefact analysis.

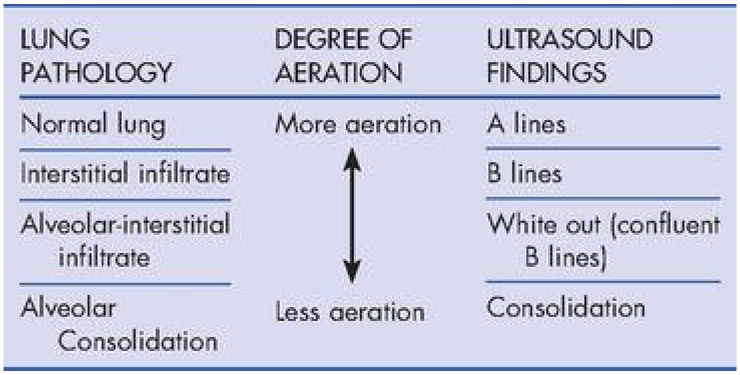
Table 40.1

Lung ultrasound re-aeration score



LUNG PATHOLOGY	DEGREE OF AERATION	ULTRASOUND FINDINGS
Normal lung	More aeration	A lines
Interstitial infiltrate	↕	B lines
Alveolar-interstitial infiltrate		White out (confluent B lines)
Alveolar Consolidation	Less aeration	Consolidation

Loss of aeration may be due to oedema, inflammation or fibrosis.

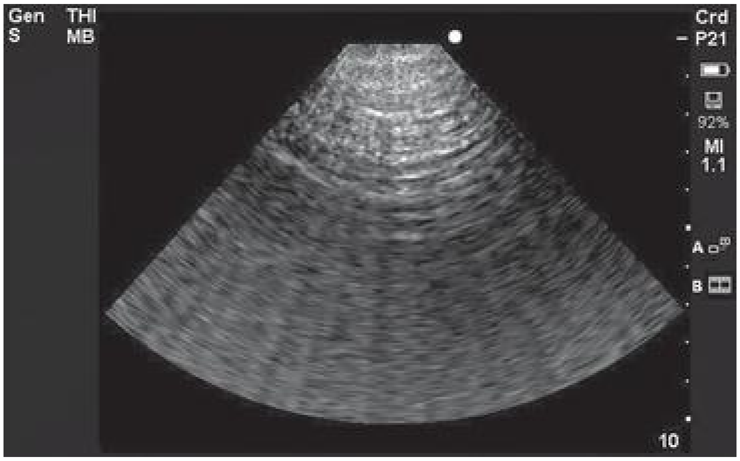


FIG. 40.21 E lines demonstrated with a 1–5 MHz phased array transducer. Note the vertical bright (hyperechoic) lines originated above the pleural line, which is poorly defined.

Lung Sliding Analysis

With tidal inflation of the normal lung, the visceral pleura slides against the parietal pleura. On ultrasound, this is seen as movement below the pleural line. The movement is best appreciated using M-mode imaging, which shows an image reminiscent of the seashore; above the pleural line there are a series of horizontal lines created by extrapleural tissue static in time (the sea), and below the pleural line there is a grainy appearance due to reflection from moving visceral pleura (the beach) (Fig. 40.22). The transducer must be held completely still on the chest wall. Diagnostic accuracy is improved if a higher-frequency transducer is used. Lung sliding is absent if the visceral pleura cannot be visualised because of air in the pleural space (pneumothorax) (Fig. 40.23), or if lung movement is abolished (e.g. pleural fibrosis, dense consolidation, atelectasis or apnoea). [7] Lung sliding may appear absent in patients with chronic obstructive pulmonary disease, or at the apices with small volume tidal ventilation. The *lung pulse sign* (see section on atelectasis) can be present only when lung sliding is absent (Fig. 40.24). [8]

Directly Visualised Pathology

Ultrasound waves are able to penetrate non-aerated tissues. Thus pleural fluid and non-aerated lung pathology (such as consolidation or complete atelectasis), can be readily visualised.

Specific Pathologies

The diagnostic accuracy of ultrasound is comparable to CT and superior to plain radiography for all the pathologies discussed in this section. The ultrasound appearance of normal lungs is characterised by the presence of A lines and lung sliding. About a quarter of normal individuals have one or two B lines at the lung bases, but other artefacts should be absent.

Pleural Effusion

Ultrasound enables the detection of small pleural effusions (<50 mL) not visible on chest radiography. Ultrasound also provides information about the nature of an effusion; septated pleural collections are better characterised with ultrasound than with CT.

Pleural fluid manifests as a relatively homogeneous dark (hypoechoic) area between the diaphragm and parietal pleura. The lung surface (visceral pleura) is seen as a regular deep border to the effusion. Aerated lung will show a bright pleural line, often with B lines, deep to the effusion. Normal lung will tend to float above an effusion, whereas collapsed or consolidated lung will float within a moderate or large effusion (Fig. 40.25).

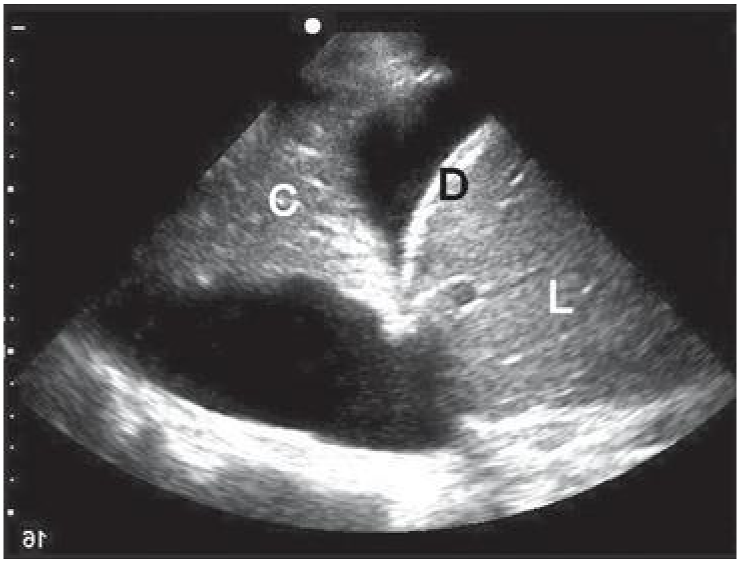

FIG. 40.25 Liver *(L)* , diaphragm *(D)* , pleural effusion and collapsed/consolidated lung *(C)* demonstrated with a 1–5 MHz phased array transducer aligned with the longitudinal axis of the patient in the basal right mid-axillary line.

Various techniques have been described to estimate the volume of pleural fluid.

Measurements are made by scanning in the basal intercostal spaces of the posterior axillary line with the transducer aligned in a transverse plane. In supine mechanically ventilated patients, a posterior pleural separation greater than 5 cm strongly predicts a drainage volume of greater than 500 mL. In semi-recumbent (15 degrees) mechanically ventilated patients, the maximum pleural separation (in mm) multiplied by 20 gives an estimate of drainage volume (in mL). [9] A multiplane method, obtained by multiplying the longitudinal extent of the effusion by the cross-sectional area at mid length, increases measurement accuracy. [10] In practice, a precise volume measurement is rarely necessary for clinical decision making.

On ultrasound the appearance of an effusion can be categorised as simple, with a uniformly anechoic (black) appearance; or complex, with echogenic material (bright dots), or septa visible within the effusion.

Transudates typically appear anechoic. The low viscosity of a transudate allows substantial movement of lung tissue with tidal ventilation. This is best appreciated as a sinusoidal pattern of the lung surface line with M-mode during tidal ventilation. The pleural line is usually smooth.

Exudates are usually, but not always, complex. The pleural line may appear thickened and irregular from pleural inflammation. A homogeneously echogenic pattern may be almost tissue-like in appearance and should not be mistaken for an area of consolidation. In septic patients, a complex appearance suggests empyema. An anechoic or minimally hyperechoic pattern is unlikely to represent empyema. A haemothorax appears as a complex effusion, with septa and areas of differing echogenicity, depending on the age of the blood.

Ultrasound guidance of thoracocentesis decreases complications and improves fluid collection rates. It allows identification of the optimal site for drainage and measurement of the depth of the pleural space. Potential hazards such as diaphragm or pleural adherences can be avoided, and the risk of intrafissural or intraparenchymal tube placement is reduced. The decision to perform thoracocentesis is based on size, the suspected nature of the effusion and clinical circumstances.

Alveolar Consolidation

Consolidated lung is not aerated and can therefore be directly visualised where it abuts the pleura, or where there is a pleural effusion between the chest wall and consolidated lung.[11], [12] Artefacts that arise from the pleural line are absent, although B lines may be seen at the edges of consolidated areas.

The echo-texture of consolidation resembles that of liver (hepatisation), although usually coarser in appearance (Fig. 40.26). When examining the right basal chest, care should be taken to distinguish between consolidated lung and liver parenchyma by clearly identifying the diaphragm (Fig. 40.25). The borders of the consolidated area may be irregular at the junction with normal lung tissue.

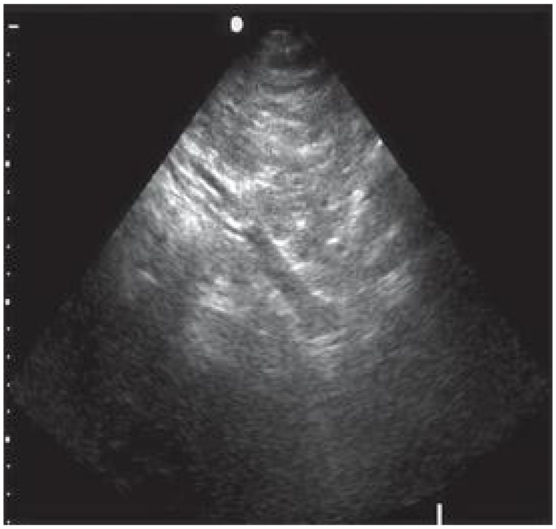

FIG. 40.26 Consolidated lung demonstrated with a 1–5 MHz phased array transducer aligned with the longitudinal axis of the patient in the mid-left mid-axillary line. Note the dark (hypoechoic) diagonal region representing the oblique fissure, and the bright (hyperechoic) punctiform air bronchograms.

Within consolidated lung, air bronchograms appear as bright (hyperechoic) punctiform or linear artefacts (Fig. 40.26). The air bronchogram artefact moves with respiration (dynamic air bronchogram), outwards (towards the transducer) with inspiration. The dynamic air bronchogram distinguishes consolidation from resorptive atelectasis. [13]

Atelectasis

Resorptive atelectasis commonly affects the dependent lung regions of mechanically ventilated patients. On ultrasound, the affected lung appears consolidated, but air bronchograms are static with respiration.

Complete lobar collapse may occur with bronchial intubation or mucus plugging. This can be detected immediately on ultrasound by the absence of lung sliding and the lung pulse sign. These signs are best appreciated using M-mode imaging with a high-frequency transducer. The lung pulse sign consists of vibrations in the M-mode trace (below the pleural line) due to transmitted cardiac pulsations (Fig. 40.24). Over time, progressive absorption of gas leads to the development of consolidated lung (resorptive atelectasis).

Alveolar–interstitial syndrome

Alveolar–interstitial syndrome encompasses disease processes with which there is predominant interstitial involvement, and partial loss of lung aeration. [5] In the acute setting, this is most often due to hydrostatic or capillary leak pulmonary oedema. Less common causes include interstitial fibrosis (interstitial pneumonia) and opportunistic infection (in immunocompromised patients). Ultrasound has a high diagnostic accuracy for alveolar–interstitial syndrome.

On ultrasound the hallmark of alveolar–interstitial syndrome is the presence of multiple (at least three) B lines largely independent of patient positioning. In mild disease, where thickening is confined to interlobular septa, the B lines are characteristically 7 mm apart (measured at the pleural line) (Fig. 40.19). With progressive pulmonary oedema and increasing alveolar flooding, or with fine fibrosis, B lines are more closely spaced (approximately 3 mm apart). In severe cases, B lines become confluent, creating a ‘white-out’ pattern (Fig. 40.20); this pattern is equivalent to ground-glass opacification on CT. Complete alveolar flooding is indistinguishable from primary alveolar consolidation.

In ARDS alveolar–interstitial syndrome is characterised by a non-uniform distribution of B lines, with areas of normal lung and areas of confluent B lines or white-out. [14] Areas of consolidation are often present, particularly in the posterobasal regions. Lung sliding is reduced, or absent, in densely affected regions and the pleural line appears irregular, thickened and coarse. A lung ultrasound *re-aeration score* based on the severity of interstitial changes (Table 40.1) provides a semiquantitative measure of positive end-expiratory pressure-induced lung recruitment. [15]

Cardiogenic pulmonary oedema shows a homogeneous distribution of B lines; pleural effusions are common, but consolidation and pleural line abnormalities are uncommon. [16] A *lung comet score* can be used to provide a semiquantitative measure of extravascular lung water. The score is obtained by adding together the number of B lines seen from each intercostal space examined over the anterior and lateral chest. Reduction in lung comet score occurs with resolution of interstitial oedema. An absence of B lines is consistent with a low pulmonary artery occlusion pressure. [17] During fluid resuscitation, the new appearance of B lines heralds the development of interstitial oedema before radiographic changes are visible.

Pneumothorax

Signs of pneumothorax should be sought anteroapically in the semi-recumbent patient, or anterobasally in the supine patient. Where there is a pneumothorax, the parietal and visceral pleura are separated by air through which ultrasound waves cannot penetrate. [7] Thus any lung pathology or artefacts abutting or arising at the visceral pleura, cannot be visualised. The combination of A lines, absent B lines, absent lung sliding and absent lung pulse sign is 100% sensitive, but not specific for pneumothorax. Detection of the edge of the pneumothorax, termed the *lung point sign* , confirms the diagnosis of pneumothorax and allows a rough assessment of its size. With the transducer held perfectly still, using 2D mode, the lung edge is seen to slide in and out of view with tidal ventilation. This can also be appreciated using M-mode imaging. The lung point sign will be visualised anteriorly with an occult or small pneumothorax, and more laterally with a moderate-sized pneumothorax. The lung point sign will be absent with a large pneumothorax, where lung sliding is absent over the entire chest. In mechanically ventilated patients, care should be taken to avoid mistaking a temporary cessation of lung sliding, due to a pause in ventilation, for true lung sliding; the lung pulse sign should be present with pauses in ventilation.

A false-positive diagnosis of pneumothorax is more likely in patients with chronic obstructive pulmonary disease. During cardiopulmonary resuscitation, the exclusion of pneumothorax may be particularly difficult because lung sliding will be absent unless there is effective ventilation, and the lung pulse sign will be absent during apnoeic periods because of the lack of cardiac contractility.

Subcutaneous emphysema is characterised by an air–liquid interface superficial to the pleural line. This creates E-line artefacts, which are similar in appearance to B lines but arise superficially to the pleural line (Fig. 40.21). The presence of subcutaneous emphysema is suggestive of pneumothorax. Unfortunately, the presence of E lines precludes further ultrasound analysis.

Diaphragmatic Dysfunction

Ultrasound provides a fast, simple and safe alternative to fluoroscopy or phrenic nerve conduction studies for the assessment of diaphragmatic dysfunction. Ultrasound techniques are based on the measurement of either the extent of diaphragmatic excursion with respiration or changes in diaphragm thickness with respiration.[18, 19]

Diaphragmatic excursion is measured with a 3–5 MHz phased array probe placed below the right or left costal margin in the mid-clavicular or anterior axillary line, directed to best visualise the posterior hemidiaphragm perpendicular to the ultrasound beam. Normal diaphragm movement with inspiration is caudal, towards the ultrasound probe in this view (Fig. 40.27). Measurements are made in M-mode. Normal values for diaphragmatic excursion during quiet spontaneous breathing are 1.8 ± 0.3 cm for males and 1.6 ± 0.3 cm for females. Inaccuracies can arise from non-perpendicular alignment of the ultrasound beam with the hemidiaphragm.

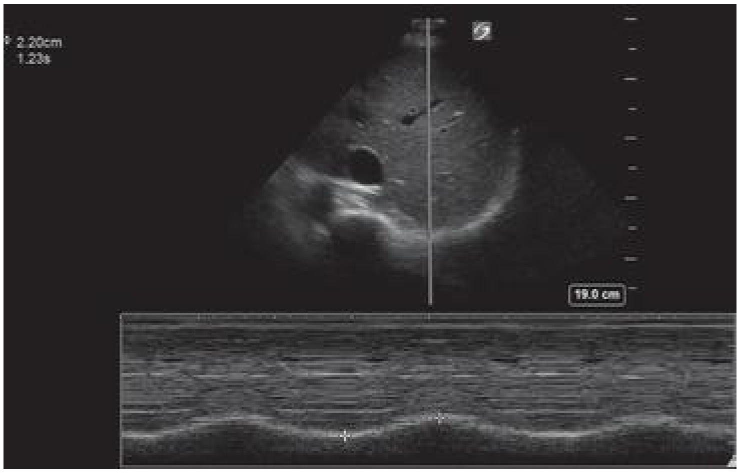

FIG. 40.27 Diaphragmatic excursion demonstrated with a 1–5 MHz phased array transducer placed over the liver in the anterior axillary line, using M-mode.

Thickness of the hemidiaphragm is measured with a linear high-frequency (7–11 MHz) probe placed over the zone of apposition of the hemidiaphragm to the rib cage, between the 8th and 10th intercostal space in the mid-axillary line (Fig. 40.28). Measurements are made in M-mode. Normal diaphragm thickness is 1.8–3 mm at end-expiration, with a greater than 30% increase during active inspiration.

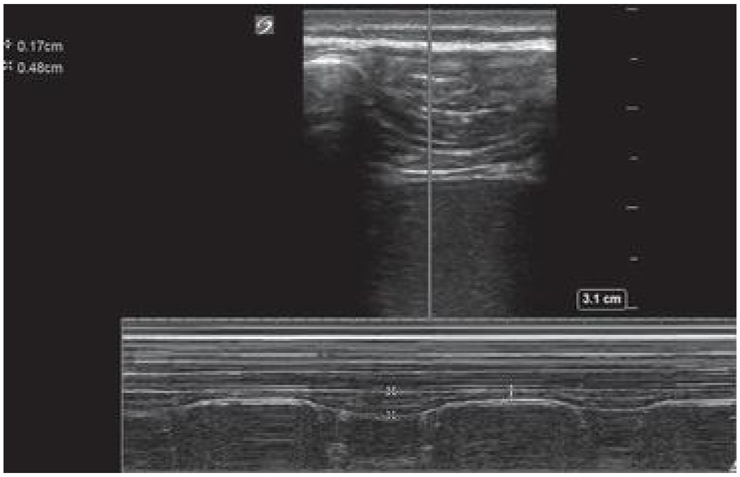

FIG. 40.28 Diaphragmatic thickening demonstrated with a 6–13 MHz linear array transducer in the mid-axillary line, using M-mode.

Assessment of diaphragmatic excursion and thickening during unsupported respiration provides a measure of work of breathing; reduced excursion and reduced thickening predict failure to wean from mechanical ventilation. Diaphragmatic atrophy (thinning and reduced excursion) can develop within a few days of controlled mechanical ventilation. Diaphragmatic paralysis manifests as absent, or paradoxical diaphragmatic excursion during unsupported respiration. Patient-ventilator synchrony may be assessed during supported mechanical ventilation by the timing of diaphragmatic excursion in relation to the timing of the airway pressure waveform.

Diagnostic Algorithms Involving Lung Ultrasound

The bedside lung ultrasound in emergency (BLUE) protocol combines lung ultrasound with deep-vein ultrasound to facilitate a diagnosis in patients with acute respiratory failure. [20] The A line, B line and lung sliding profile on lung ultrasound are used to differentiate pulmonary oedema, pneumonia and pneumothorax. In patients with lung sliding and A lines throughout the chest (normal lung ultrasound), the presence of venous thrombosis on deep-vein ultrasound makes pulmonary embolism the likely cause of acute respiratory failure. Direct diagnosis of pulmonary embolism with lung ultrasound is unreliable. [21]

The fluid administration limited by lung sonography (FALLS) protocol combines lung ultrasound with echocardiography to aid the diagnosis of the cause of acute circulatory failure. [20] Firstly, obstructive shock is excluded by ultrasound examination for tension pneumothorax, pericardial tamponade and pulmonary embolism (right ventricular dilatation). Secondly, cardiogenic shock is excluded by examination for signs of left heart disease and B lines. Finally, patients with hypovolaemic or distributive shock will have A lines, indicating that fluid resuscitation can safely be administered, titrated until B lines appear. In this way, fluid administration is limited by the development of pulmonary oedema, which coincides with loss of fluid responsiveness. For undifferentiated hypovolaemic shock, abdominal ultrasound is added to detect free peritoneal fluid and abdominal aortic aneurysm.

Computed tomography

A CT scanner consists of an X-ray tube, which rotates around the patient, and an array of X-ray detectors opposite the tube. At the same time the patient examination couch slides through the CT gantry aperture so that a continuous data set or ‘spiral’ of information is acquired during a single breath hold. With chest CT the large difference in X-ray attenuation between vessels and surrounding air in the lung, and between vessels and surrounding fat in the mediastinum, reduces the need for contrast injection in many instances.

Contrast is required to distinguish between hilar vessels and a soft-tissue mass, or to detect intravascular pathology (e.g. pulmonary embolism or aortic intimal tear). Rapid scanning protocols with automated injectors improve contrast enhancement of vascular structures at the expense of enhancement of solid organs because of the rapidity of scanning. Timing of image enhancement is vital for accurate diagnosis of pulmonary embolism. When examining inflammatory lesions it may be necessary to delay scanning by 60 seconds to allow contrast to diffuse into the extravascular space.

High-resolution CT (HRCT) is a technique where images are collimated to a much thinner 1 mm slice, compared to the usual 3–5 mm slices with conventional CT. HRCT provides enhanced image resolution for the evaluation of diffuse lung disease including ARDS.

Indications for CT Chest

The need to transport the patient out of the ICU and position them horizontally, as well as exposure to radiation (plus contrast), make CT a selected examination for specific clinical situations.

CT pulmonary angiography (CTPA) is the investigation of choice for the diagnosis of pulmonary embolism (Fig. 40.29). The CTPA can demonstrate the pulmonary clot burden and identify signs of acute right heart strain.

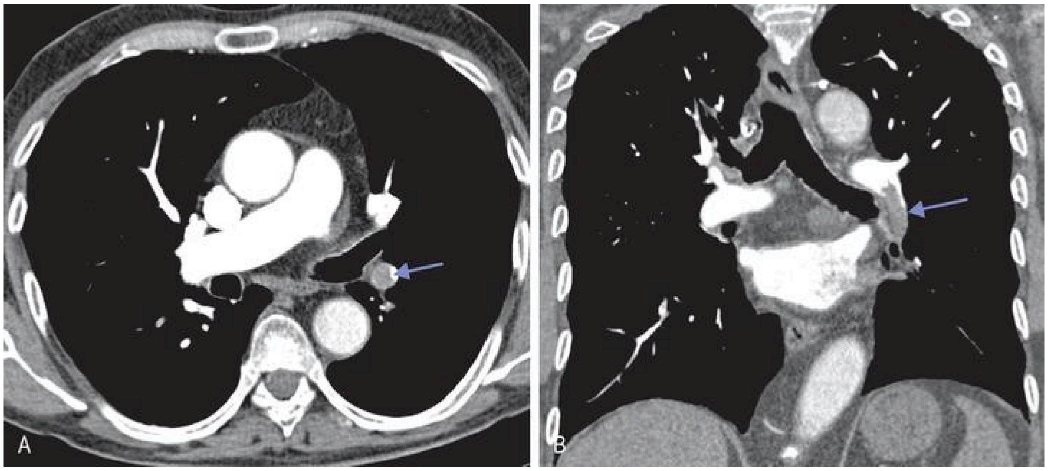

FIG. 40.29 Pulmonary embolism: (A) axial and (B) coronal computed tomographic image of an embolus in the left lower lobe pulmonary artery *(arrows)* .

Chest CT angiography (usually as part of a pan scan) is indicated as part of the initial evaluation of any trauma patient with critical injuries (Figs. 40.30 – 40.33). [22] Chest CT angiography is also indicated for suspected major vessel disorders (Fig. 40.34). [23] Indications for chest CT in critically ill patients with lung disease include:

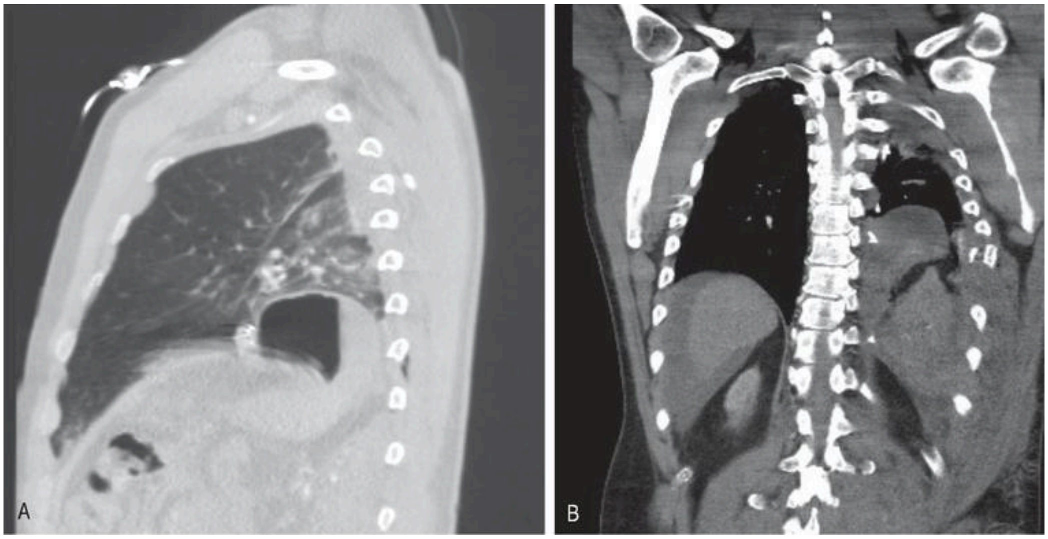

FIG. 40.30 Traumatic diaphragmatic hernia on computed tomography. Axial lung windows demonstrate the stomach is above the diaphragm. The defect is best seen on the coronal soft-tissue reformats.

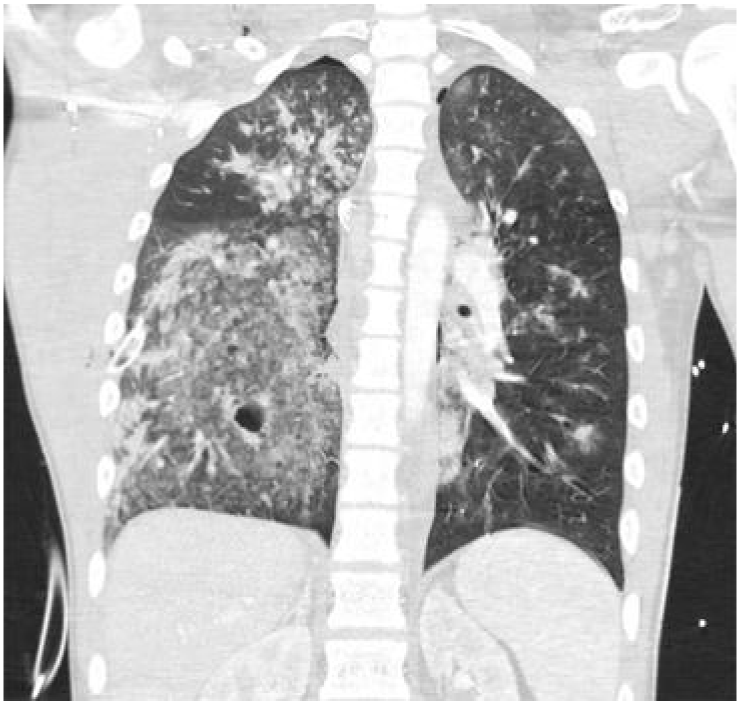

FIG. 40.31 Pulmonary contusion. Computed tomography shows diffuse ground-glass opacity of the right lung, and there is also a laceration causing a traumatic pneumatocele (air cyst) of the right lower lobe.

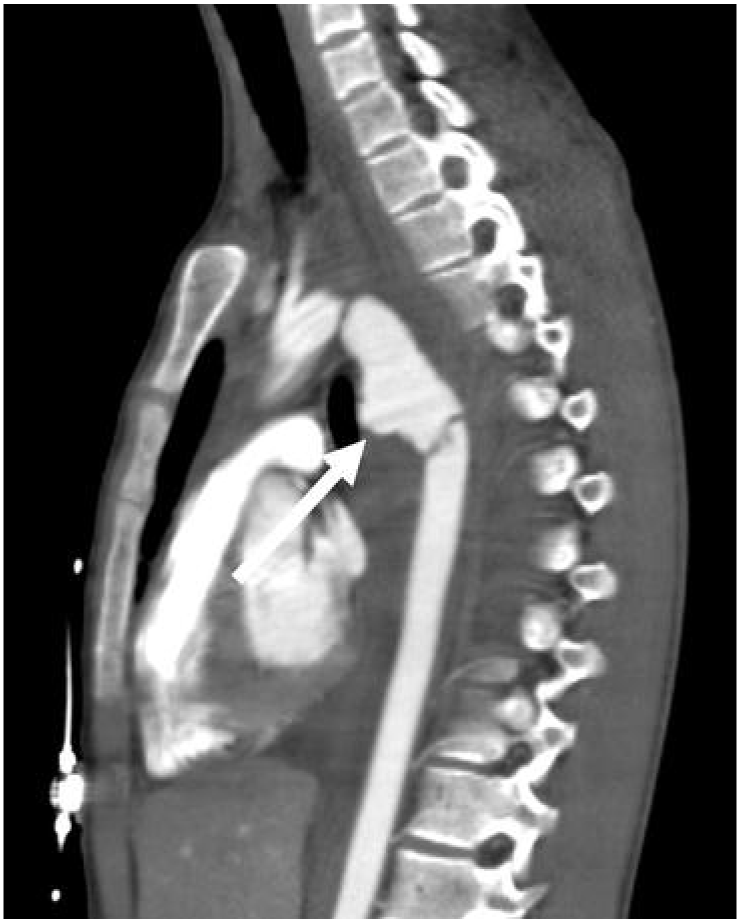

FIG. 40.32 Traumatic aortic injury on computed tomography thoracic angiogram. Usually best seen on sagittal reformats, there is an intimal tear leading to abnormal contour, causing pseudoaneurysm formation *(arrow)* . There is surrounding haematoma.

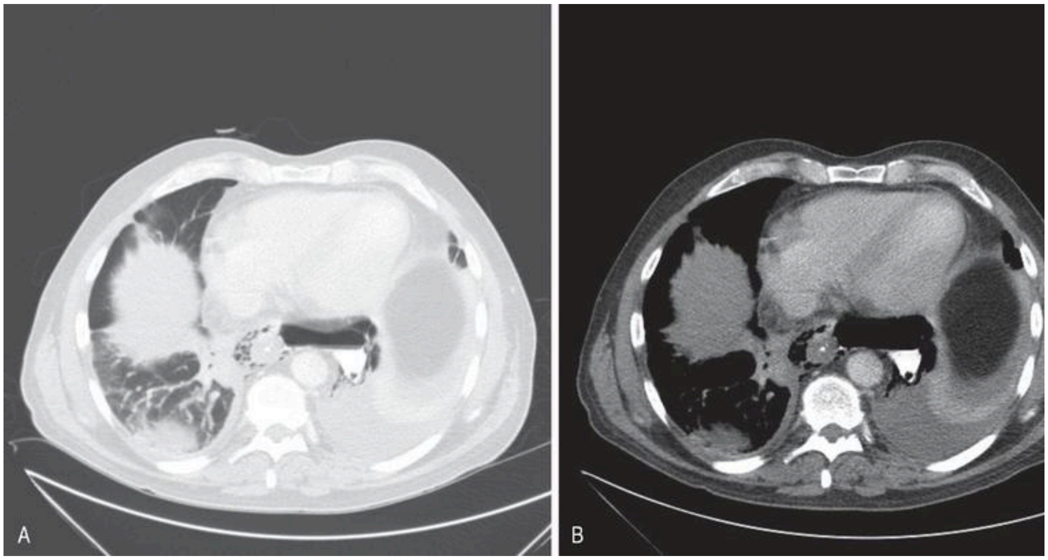

FIG. 40.33 Oesophageal rupture. The patient swallowed oral contrast just prior to the computed tomography scan. The contrast has leaked into the posterior mediastinum, to the left of the lower oesophagus adjacent to the gastro-oesophageal junction. There is a pre-existing pneumomediastinum due to oesophageal rupture.

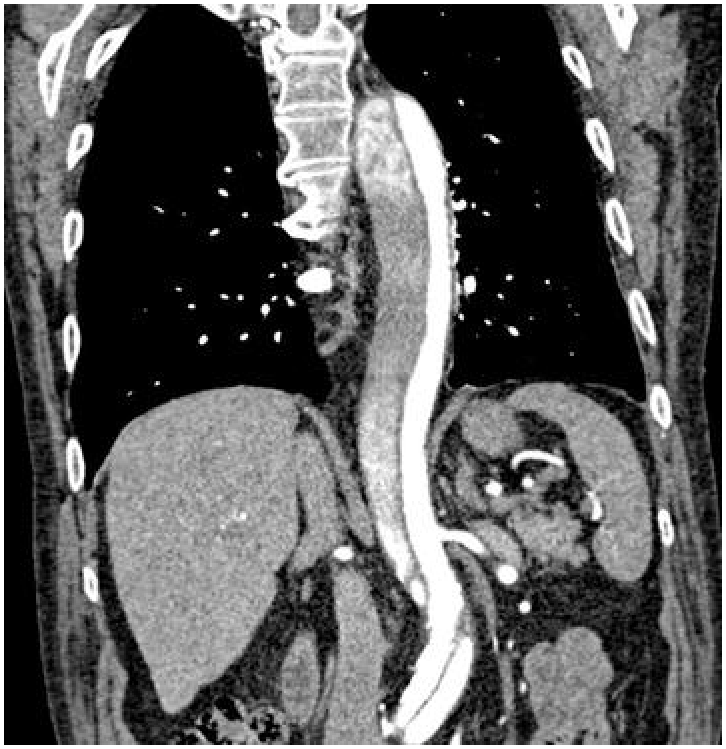

FIG. 40.34 Aortic dissection. Coronal computed tomographic image showing intimal flap in the descending aorta.

Acute Respiratory Illness

In patient with severe pneumonia, CT can provide good delineation of the extent of parenchymal disease, abscess or parapneumonic effusion. Contrast improves CT evaluation of pleural involvement such as empyema. However, ultrasound may be sufficient to identify the presence and nature of a pleural collection and guide drainage.

Extensive, multiple or diffuse infiltrates on the chest radiograph should prompt consideration of an atypical or opportunistic infection, particularly in the immunocompromised patient. [24] Chest CT may show features characteristic of a particular causative organism (e.g. Pneumocystis jirovecii infection, aspergillosis, mucormycosis, cytomegalovirus or mycobacterium). Alternatively, CT may indicate a non-infectious cause, such as organising pneumonia, drug-induced lung disease or radiation pneumonitis. [25]

ARDS

In ARDS CT shows extensive ground-glass opacities and consolidation with a gravitational graded increase in density of the infiltrates (Fig. 40.35). [14], [25] Infection is common in ARDS but may be difficult to determine radiologically. The presence of non-dependent consolidation, abscess, empyema or mediastinal involvement suggests the presence of infection. Barotrauma manifests as mediastinal and interstitial emphysema, or pneumothorax (Fig. 40.7). The dilation of narrower airways within regions of ground-glass opacification is indicative of the development of fibrosis. In imaging literature, this is termed traction bronchiectasis.

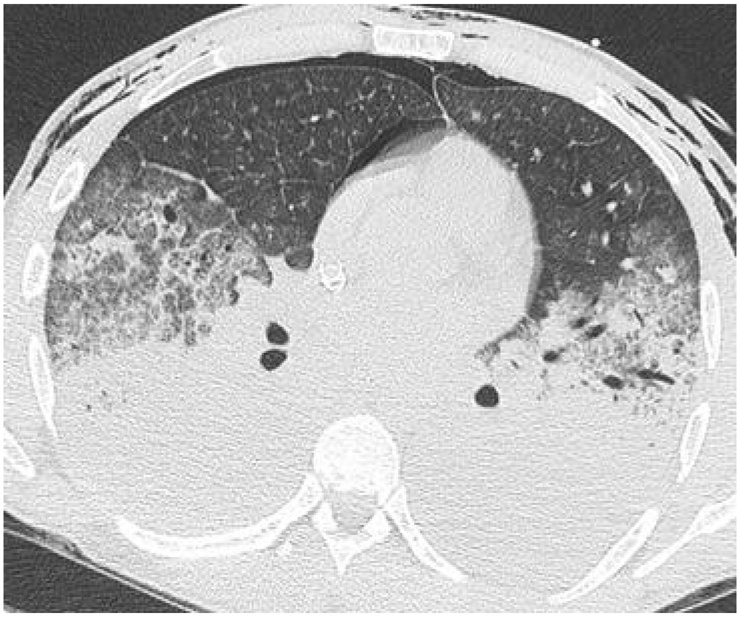

FIG. 40.35 Computed tomography of a patient with acute respiratory distress syndrome. Note the marked anterior-to-posterior-density gradient. The anterior lung is of almost normal density, becoming of ground-glass attenuation in the mid part of the lung before fading into consolidation posteriorly. There are small pneumothoraces bilaterally and surgical emphysema.

Diffuse Lung Disease

HRCT may assist in establishing the initial diagnosis of diffuse parenchymal lung disease (e.g. interstitial lung disease) or help distinguish an acute exacerbation from other causes of deterioration such as infection, pulmonary oedema or malignancy.

Haemoptysis

In clinically stable patient with haemoptysis, CT with contrast is the preferred investigation to identify the source (bronchial circulation in 90% of cases) and the cause (e.g. tuberculosis or malignancy) of bleeding. CT angiography improves bronchial vessel opacification, and also detection of a pulmonary artery source of bleeding (10% of cases).

CT Signs of Lung Pathology

- *Consolidation* : is defined as increased attenuation of lung parenchyma that obscures bronchovascular structures. Consolidation signifies alveolar flooding with pus, fluid or blood, and thus has a broad range of potential causes.
- *Ground-glass opacity* : is defined as increased attenuation of the lung parenchyma without obscuration of bronchovascular structures. Acute onset of diffuse ground-glass opacity without other alveolar or interstitial findings is most likely caused by cardiogenic pulmonary oedema, ARDS or opportunistic infection (immunocompromised patients).
- *Small pulmonary nodules (<1 cm)* : centrilobular or randomly distributed nodules are commonly associated with infection. Centrilobular nodules connected by branching linear opacities (referred to as tree-in-bud pattern) are characteristic of bronchiolar inflammation.
- *Halo sign* : refers to an area of ground-glass opacification surrounding a mass or nodule, and is suggestive of angio-invasive fungal infection (e.g. *Aspergillus* infection).
- *Reverse halo sign* : refers to an area of ground-glass opacification surrounded by consolidated granulomatous tissue. It may be seen in organising pneumonia.
- *Reticular pattern, honeycomb cysts and traction bronchiectasis* : these three features, together with loss of lung volume, are the hallmarks of pulmonary fibrosis. Rarely they may be seen in the recovery phase of diffuse alveolar damage caused by ARDS and ventilator-induced lung injury. Radiologically they are defined as a

network of fine lines within the secondary pulmonary lobule, subpleural clustered cysts measuring 3–5 mm and irregular bronchial and bronchiolar dilatation, respectively. [26]

The Post-operative Chest

Thoracic Complications of General Surgery

- *Atelectasis* : is the commonest pulmonary complication of thoracic or abdominal surgery. The chest radiograph usually shows elevation of the diaphragm due to poor inspiration. Linear opacities are present in the lower zones, representing a combination of subsegmental volume loss and consolidation. The features of atelectasis usually appear within 24 hours post-operatively and resolve within 2 to 3 days in uncomplicated cases.
- *Pleural effusion* : It is common immediately following abdominal surgery and usually resolves within 2 weeks. Effusions due to subphrenic infection usually occur later.
- *Pneumothorax* **:** It is usually a complication of mechanical ventilation or central venous catheter insertion. It may also complicate nephrectomy.
- *Pulmonary aspiration* : Microaspiration is common during anaesthesia, but usually not clinically significant. More severe aspiration causes pneumonitis with patchy basal and peri-hilar consolidation on the chest radiograph. Clearing occurs within a few days unless there is superinfection.
- *Pulmonary oedema* : It may be due to cardiac dysfunction, excessive fluid administration or ARDS.
- *Subphrenic abscess* : It usually produces elevation of the hemidiaphragm, pleural effusion and basal atelectasis. Loculated gas may be seen below the diaphragm. Subphrenic abscess is best demonstrated by CT or ultrasound.
- *Subphrenic air* : Pneumoperitoneum may persist for about two weeks following laparotomy. Increasing volumes of air should

prompt consideration of CT evaluation for perforated abdominal viscus.

Post Cardiac Surgery

Most cardiac operations are performed through a sternotomy incision, and wire sternal sutures are often seen on the post-operative radiographs. Mitral valvotomy is rarely performed via a thoracotomy incision. This route is also used for surgery of coarctation of the aorta, patent ductus arteriosus, Blalock–Taussig shunts and pulmonary artery banding.

Widening of the cardiovascular silhouette is usual and represents bleeding and oedema. Marked or progressive widening of the mediastinum suggests significant haemorrhage and may be associated with pericardial effusion. (Fig. 40.14).

Left basal opacification almost always indicates atelectasis. This usually resolves over a week or two. Small pleural effusions are also common in the immediate post-operative period. White-out of one hemithorax may be due to massive haemothorax or lung collapse. The former is associated with the flattening of the hemidiaphragm and may displace the mediastinum towards the contralateral side. The latter may be associated with mediastinal shift towards the affected side; the position of the endotracheal tube should be checked for inadvertent endobronchial intubation.

Some air commonly remains in the pericardium following cardiac surgery so that the signs of pneumopericardium may be present. Violation of left or right pleural space may lead to a pneumothorax. Subdiaphragmatic air is sometimes seen due to the involvement of the peritoneum at the inferior extent of the sternotomy incision or placement of mediastinal and pleural drains. The air may only be visible on an erect chest radiograph and not on the initial post-operative supine radiograph. Subdiaphragmatic air is of no pathological significance in the early post-operative period (Fig. 40.1).

Damage to a major lymphatic vessel may lead to a chylothorax or a more localised chyloma. Phrenic nerve damage may cause paresis or paralysis of a hemidiaphragm.

Surgical clips or other metallic markers have sometimes been used to mark the ends of coronary artery bypass grafts. Prosthetic heart valves are usually visible radiographically, but they may be difficult to see on an underpenetrated radiograph.

Sternal dehiscence may be detected radiographically by the presence of a linear lucency in the sternum and a change in the position of the sternal sutures on consecutive radiographs. Typically, the diagnosis is determined clinically and may be accompanied by osteomyelitis. It is possible to fracture the first or second rib when the sternum is separated. The significance of this observation is that it may explain post-operative chest discomfort. Acute mediastinitis may complicate mediastinal surgery, although it is more commonly associated with oesophageal perforation or surgery. Radiographically there may be mediastinal widening or pneumomediastinum, and these features are best assessed by cross-sectional imaging.

Post-Pneumonectomy

The initial post-operative radiograph will show an air-filled pneumonectomy space with volume loss. Thereafter, the pneumonectomy space fills with fluid, at a rate of approximately 2 ribs per day on an erect radiograph. The residual air bubble in the pneumonectomy cavity should shrink over time. If, however, the air bubble increases in size, this is indicative of a bronchopleural fistula, and a CT is indicated. If the pleural effusion rapidly increases in size, this may indicate a haemothorax, which could be life threatening and should also be evaluated by CT.

Oxygen therapy, humidifiers and inhalation therapy

Shailesh Bihari, Steven Galluccio and Andrew Bersten

Oxygen Therapy Apparatus and Devices

In the hypoxaemic self-ventilating patient, delivery of oxygen to the alveoli is usually achieved by increasing the Fi_{o_2}. Most commonly this involves the application of one of the many varieties of oxygen masks to the face, such that it covers the nose and mouth. There are other methods (e.g. nasal cannulae), but each needs to fulfil the same basic requirements.

Most of the simpler devices (e.g. plastic masks and nasal cannulae) deliver oxygen at relatively low oxygen flow rates relative to peak inspiratory flows (25–100+ L/min). The final Fi_{o_2} delivered is heavily influenced by the entrainment of environmental air, which dilutes the set Fi_{o_2}. From a physical principles perspective, the actual concentration of oxygen delivered is determined by the interaction between the delivery system and the patient's breathing pattern. The Fi_{o_2} that reaches the alveolus is therefore unpredictable. Factors that influence this can broadly be divided into patient factors and device factors (Box 41.1).[1,2]

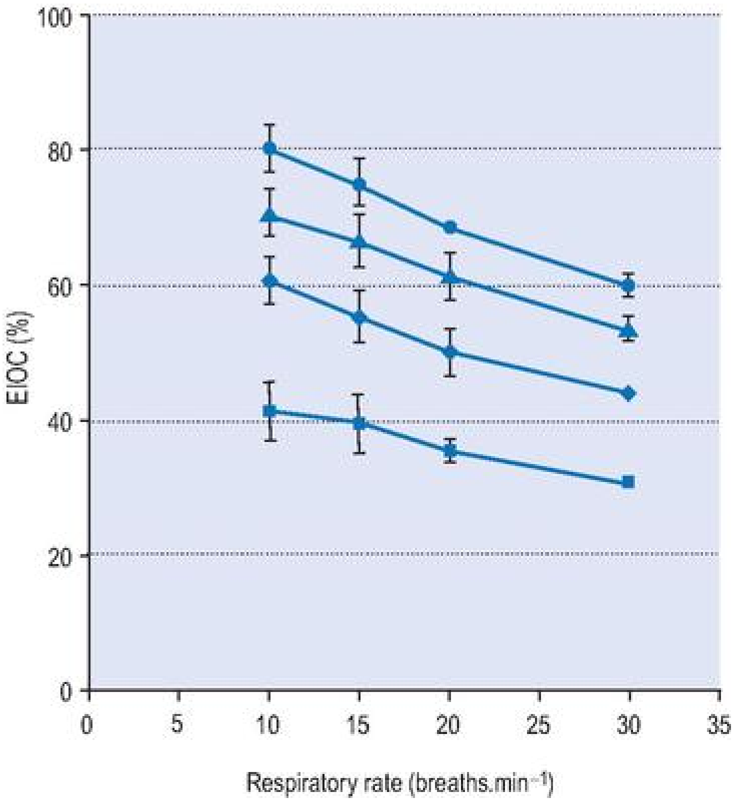
Box 41.1

Factors that influence the Fi_{O_2} delivered to a patient by oxygen delivery devices

Patient factors	**Device factors**
Inspiratory flow rate	Oxygen flow rate
Presence of a respiratory pause	Volume of mask
Tidal volume	Air vent size
	Tightness of fit

From Leigh J. Variation in performance of oxygen therapy devices. *Anaesthesia* . 1970;25(2):210–222.

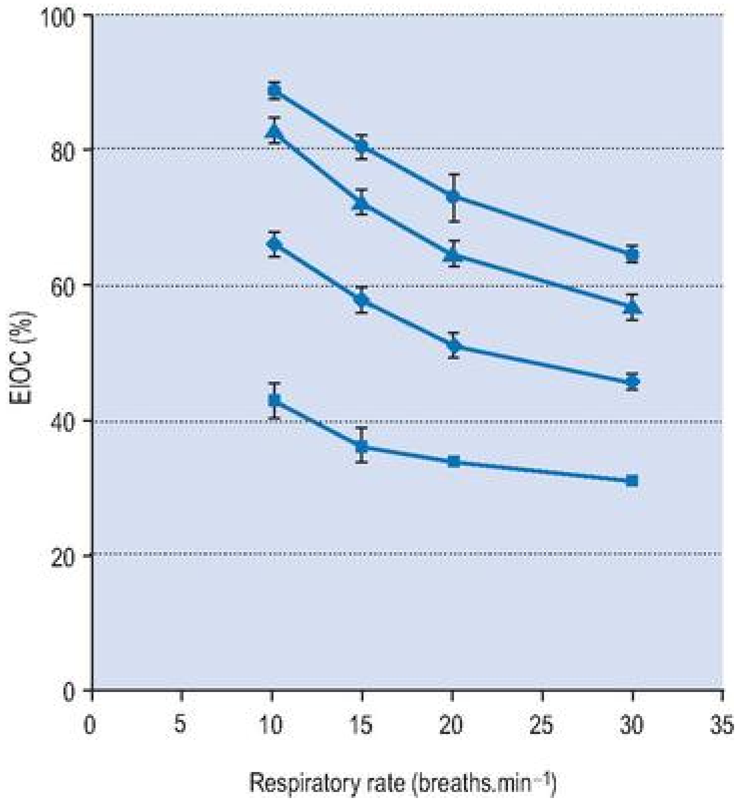
In the hypoxaemic patient, it is common to find significant increases in inspiratory flow rates, as well as an absence of the respiratory pause. This can result in the actual Fi_{o_2} at the alveolus being significantly less than that thought to be delivered. This is due to a greater proportion of the inhaled gas being entrained air when the patient's inspiratory flow rate increases. The normal peak inspiratory flow rate (PIFR) is 25–35 L/min; in respiratory distress, this can increase eightfold, greater than 200 L/min. [3] The greater the inspiratory flow rate, the lower the alveolar Fi_{o_2} . This is particularly true for the variable performance-type masks but is seen even in the more 'reliable' Venturi-type masks, particularly when higher Fi_{o_2} inserts are used. The presence of a valve-controlled reservoir bag on a 'non-rebreather' semi-rigid plastic mask should compensate for high inspiratory flows – hence the belief that such masks can deliver 100% oxygen. However, this is not the case, and in models of human ventilation, such masks do not seem to confer significant extra oxygen delivery ability greater than that of semi-rigid plastic masks without a reservoir bag (Figs. 41.1 and 41.2). [4] The failure of oxygen masks to deliver the desired Fi_{o_2} can be improved either by having a high enough oxygen flow rate and reservoir to compensate for the high inspiratory flow rate (e.g. high-flow nasal cannulae [HFNC]) or by sealing the upper airway (nose and mouth) from the environment (e.g. the continuous positive airway pressure [CPAP] mask). Indeed, there is evidence supporting the hypothesis that some of the improvements in oxygenation seen with CPAP ventilation may be due to the eradication of entrainment of environmental air rather than the positive airway pressure exerted by the CPAP valve. [4]



The graph features two axes. The vertical axis reads End Tidal Oxygen Concentration in percent and extends from zero to one hundred. The horizontal axis reads Respiratory Rate in breaths per minute and extends from zero to thirty five. Four lines with data points plot the relationship between these variables. Each line trends downward as the respiratory rate increases. The lines include error bars at each data point, which extend vertically.

FIG. 41.1 The performance of a Hudson mask on a model of human ventilation at a tidal volume of 500 mL and four oxygen flow rates (2 L/min [□], 6 L/min [◊], 10 L/min [Δ] and 15 L/min [o]). As the respiratory rate increases, the effective inspired oxygen concentration (EIOC) deteriorates. (From Wagstaff TAJ, Soni N.

Performance of six types of oxygen delivery devices at varying respiratory rates. *Anaesthesia* . 2007;62(5):492–503.)



The graph features two axes. The vertical axis reads End Tidal Oxygen Concentration in percent and extends from zero to one hundred. The horizontal axis reads Respiratory Rate in breaths per minute and extends from zero to thirty five. Four lines with data points plot the relationship between these variables. Each line trends downward as the respiratory rate increases. The lines include error bars at each data point, which extend vertically to indicate variability.

FIG. 41.2 The performance of a Hudson non-rebreather mask on a model of human ventilation at a tidal volume of 500 mL and four oxygen flow rates (2 L/min [□], 6 L/min [◊], 10 L/min [Δ] and 15 L/min [o]). As the respiratory rate increases, the effective inspired oxygen concentration (EIOC) deteriorates. Note also how the curves of the graph are similar to the Hudson mask without the reservoir bag, implying no superiority with its addition. (From Wagstaff TAJ, Soni N.

Performance of six types of oxygen delivery devices at varying respiratory rates. *Anaesthesia* . 2007;62(5):492–503.)

Heater

FIG. 41.3 Hot-water ‘blow-by’ humidifier.

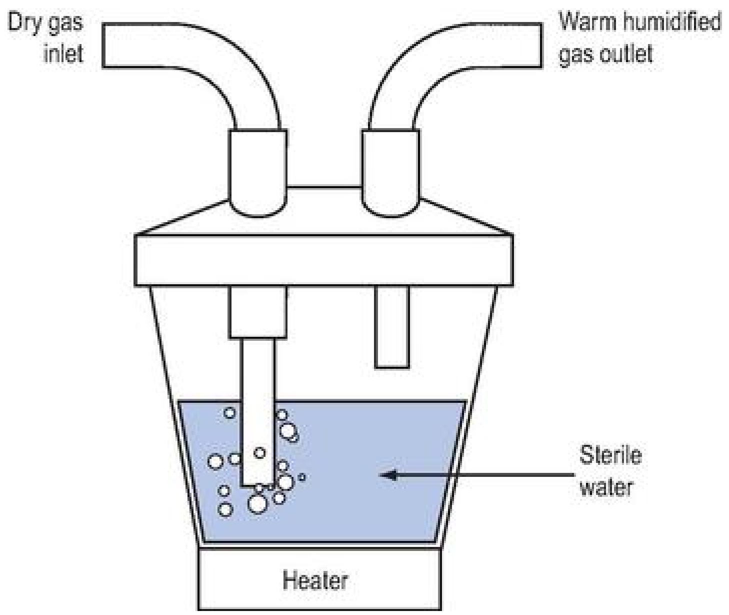

FIG. 41.4 Hot-water ‘cascade’ or ‘bubble’ humidifier.

In summary, the use of non-sealing oxygen masks and cannulae should be guided by the patient’s requirements and response to therapy, rather than a belief that the concentration being delivered is reaching the alveolus. This can be particularly important in the treatment of patients whose ventilatory drive is sensitive to PO_2 levels.

Oxygen Delivery Devices

Methods of delivering oxygen to conscious patients with no instrumentation to their airway can broadly be divided into four categories: (1) variable performance systems, (2) fixed performance systems, (3) high-flow systems and (4) others. With the exception of the intravascular devices, all comprise similar component parts:

1. *Oxygen supply:* oxygen can be delivered from pressurised cylinders, hospital supply from cylinder banks or vacuum-insulated evaporator or oxygen concentrator.
2. *Oxygen flow control:* oxygen supplied to the device is controlled by some sort of valve, often with an associated flow meter.
3. *Connecting tubing:* both from the supply to the flow control and from the flow control to the device, the type and size of the tubing

are important. Small-bore tubing can limit oxygen flow when high flow is intended. In some systems, the connecting tubing can also act as a reservoir (e.g. Ayre's T-piece). Some devices require specialised tubing with appropriate end attachments, such as the Schräeder valves required for connecting to the wall oxygen supply.

4. *Reservoir:* all oxygen delivery devices have some sort of reservoir. In a simple oxygen mask, it is the mask itself. Some low-flow CPAP circuits have a balloon reservoir. Nasal cannulae use the nasopharynx as a reservoir. An oxygen tent uses the volume of the tent as a large reservoir. The effectiveness of the reservoir in 'storing' oxygen ready for the next inspiratory effort is one of the important factors in governing its ability to deliver the desired oxygen concentration. The oxygen tent is a good example of the effectiveness of a large reservoir because it eliminates air entrainment, whatever the patient's PIFR. Thus, the oxygen flow rate does not have to be high, but just enough to ensure that CO_2 re-breathing is abolished. Indeed, it is the retention of CO_2 that can be the major problem if gas is expired into the reservoir.
5. *Patient attachment:* the patient is connected to the oxygen supply and reservoir such that the device delivers oxygen to the airway – either by directly covering the upper airway (e.g. plastic mask/head box), intranasally or by increasing the oxygen concentration in the wider environment as in an oxygen tent.
6. *Expired gas facility:* expired gas from the patient needs to be allowed to dissipate into the environment and not be retained in the system to be inspired at the next inspiratory effort. Most masks achieve this by having a small reservoir capacity and holes in the plastic to allow the gas to exit. One-way valves, as in the non-rebreather type reservoir mask, aid in unidirectional flow of gas away from the patient. High-flow T-piece systems like those used in a CPAP system use the high flow to remove the gas down an expiratory limb and into the environment.
7. *Humidification:* most systems use the physiological humidification properties of the nasopharynx and trachea. However, high-flow systems may overcome this, leading to drying of the airway and

secretions, which can be uncomfortable and undesirable. Artificial humidification (and warming) should be employed, using devices such as a water bath or heat and moisture exchanger (HME). See below

8. *Oxygen concentration monitor:* some systems have an oxygen concentration monitor incorporated in the apparatus (e.g. a fuel cell). This allows the much more accurate monitoring Fi_{o_2}, but this is dependent on where in the system it is placed and adds bulk and expense to the oxygen delivery method.

Variable Performance Systems

Typically, these are non-sealed masks or nasal cannula systems, which deliver oxygen at low gas flows. The reservoir is usually small, consisting of the volume of the mask in the case of the semi-rigid type, or the nasopharynx as in the nasal cannula. The entrainment of environmental air is important in their delivery capability and has to be considered when being used.

Nasal cannula

The proximity of the reservoir, the nasopharynx, means that these systems are particularly sensitive to changes in inspiratory flow rate and particularly the loss of the respiratory pause. However, for mild hypoxia, they are tolerated well by patients who can eat and drink with them in situ. They can cause drying of the nasal mucosa when used at higher flow rates, and newer systems are available that can humidify and warm the inspired oxygen. They are cheap and easy to use, with no risk of CO_2 retention. A traditional nasal cannula can only effectively provide only up to 4 to 6 litres per minute of supplemental oxygen, which equates to a maximum Fi_{o_2} of approximately 0.37 to 0.45.

Simple semi-rigid plastic masks (variable performance masks)

The most commonly used type of oxygen mask, these are cheap and easy to administer. The reservoir comprises the mask, and re-breathing of CO_2 can therefore occur if used at oxygen flow rates less than 4 L/min. It delivers an

Fi_{O_2} of 0.35–0.60 at flow rates of 5 to 10 litres per minute. A maximum Fi_{O_2} of around 0.6 can be achieved, which will be lower in the presence of respiratory distress.

Tracheostomy masks

These semi-rigid plastic masks act in the same way as their facial counterparts and achieve similar Fi_{O_2}. However, the delivery they achieve is very dependent on the presence of a tracheostomy tube and the inflation status of its cuff. If absent, or if the cuff is deflated, then air from the nasopharynx will mix with that being delivered to the tracheostomy and further dilute the Fi_{O_2}.

T-Piece system

These simple systems, consisting of an inspiratory limb and expiratory limb forming the bar of the ‘T’, can be used with endotracheal tubes (oral, nasal or tracheostomy) or with a sealed CPAP-type mask. The oxygen flow rate needs to be high enough to match the patient’s PIFR so as to prevent re-breathing of expired gas and thus potential entrainment of air from the expiratory limb. The seal of the mask or tube cuff is important also to prevent entrainment of air.

Fixed Performance Systems

These systems are so-called because their delivery of oxygen is independent of the patient factors outlined previously.

Venturi-type masks

Oxygen concentration is determined by the Venturi principle: oxygen passing through a small orifice entrains air to a predictable dilution. The Fi_{O_2} is adjusted by changing the Venturi ‘valve’ and setting the appropriate oxygen flow rate. Although the Venturi effect can deliver 40–60 L/min, this is possible only at the lower Fi_{O_2} valves (e.g. at Fi_{O_2} of 0.24 the total flow rate is approximately 53 L/min at an inflow of 2 L/min oxygen diluted by 51 L/min entrained air), and oxygen flow rate falls as the Fi_{O_2} increases. Thus, in respiratory distress associated with hypoxaemia, the reduction in oxygen flow rate can lead to failure despite a higher Fi_{O_2} setting. The larger orifice leads to the system behaving more like a simple mask.

Anaesthetic breathing circuits

These circuits (e.g. Mapleson A, B, C, D and E) are not commonly outside of an operating theatre but certain modifications such as Water’s circuit might still be used in ICU. Water’s circuit is similar in construction to the Mapleson B/C, but the main tubing is shorter. A fresh gas flow equal to twice the minute ventilation is required to prevent re-breathing. Delivery of oxygen to the patient with a Mapleson circuit via face mask takes considerable skill and training. Bag inflation is reliant on continuous fresh gas flow and a tight mask seal, without which the bag will not maintain adequate inflation (or will empty completely) rendering ventilation ineffective (or impossible). However, the use of the Mapleson circuit is a skill worth acquiring because there is no inspiratory valve to overcome (unlike the bag valve mask [BVM] discussed later), minimising the inspiratory effort required during spontaneous breathing.

Self-Inflating bag valve mask

By design, self-inflating BVMs are not reliant on fresh gas flow or mask seal to deliver a hand-ventilated inspiratory volume; this is critical during patient transport as a minimum of 21% oxygen (room air) can be delivered under positive pressure if there is a failure of oxygen supply. Despite the BVM being easier to use than Mapleson circuits by the non-expert, it has disadvantages, hence vigilance is required to establish a tight mask seal and to ensure the oxygen source is connected, turned on and filling the reservoir bag. In addition, a self-ventilating patient in respiratory failure may not be able to open the one-way valve to achieve effective ventilation; hence inspiratory effort often needs to be assisted by hand, which can be challenging, especially when two hands are required for a mask seal. There is also no direct feedback from the self-inflating bag itself to alert the operator to a loss of mask seal or inform them of ventilation adequacy. A blow-off valve, usually set at 60 cm H_2O, is the only means of detecting high airway pressure.

High-Flow Systems

High-flow oxygen therapy, originally developed in the neonatal and paediatric settings, is a relatively recent innovation in critically ill adult patient.[5] It delivers warm humidified high-flow oxygen at flow rates between 15 and 60 L/min through a small nasal or face mask interface. Humidification of this high gas flow rate contributes to a remarkably high degree of tolerance, and, rather than cyclically increasing the upper airway-inspired oxygen concentration which is then diluted by entrained air (standard oxygen therapy), it offers (1) a gas flow rate closer to the subjects inspiratory flow rate, (2) flow-dependent CPAP with increased end-expiratory lung volume, and (3) washout of upper airway CO_2 leading to decreased physiological dead space, with both latter mechanisms possibly contributing to reduce the work of breathing.[6-8] A number of investigators have shown that HFNC is comfortable and effective at improving oxygenation.[9] The current evidence suggests that in patients with hypoxaemic respiratory failure, high-flow oxygen therapy prevents reintubation after extubation when compared with standard oxygen therapy.[10] However, a high proportion of patients with de novo acute hypoxaemic respiratory failure require intubation when initially managed with high-flow oxygen therapy[11]; and when intubation is delayed in these patients, it is associated with increased intensive care unit (ICU) mortality.[12] Moreover in patients with acute hypoxemic respiratory failure and COVID-19, there was no significant difference between an initial strategy of high-flow oxygen therapy compared with conventional oxygen therapy.[13] This reinforces the need for an appropriate high-acuity clinical environment and an appropriately trained team to manage patients with acute hypoxaemic respiratory failure with high-flow oxygen therapy.

Positive-pressure devices

Non-invasive ventilation (NIV) delivers oxygen with some element of positive pressure exerted during the respiratory cycle. It does not require instrumentation of the airway and is delivered either by a tight-fitting mask to the face or nose or as a helmet. The simplest CPAP system is a T-piece with a positive-pressure valve attached to the expiratory limb. Other methods are also available; some use a balloon reservoir rather than a high-flow oxygen generator (Mapleson A). CPAP helps to improve functional residual capacity (FRC) and compliance.[14] There is no air entrainment, which contributes to the initial rapid improvement. Theoretically, the positive pressure aids alveolar recruitment. A potential problem with the T-piece CPAP systems is that the oxygen flow rate has to be adjusted to the patient's PIFR so as to prevent closure of the valve, increasing the inspiratory work of breathing. Other methods of NIV, such as bilevel positive airway pressure (BPAP) deliver oxygen at flows that should match the patient's demand (see Chapter 43).

Management of Oxygen Therapy

In the correct situations, oxygen is a life-saving drug/therapy. It remains part of the initial resuscitation and ongoing management of the critically unwell. In the United Kingdom at any one time, 15%–17% of all hospital inpatients will be receiving oxygen.[15] However, oxygen can have detrimental effects in certain patient groups and/or situations, and this may result in significant morbidity or mortality.

Targeted Oxygen Therapy

The need for oxygen to prevent tissue hypoxia and cellular dysfunction is clear. However, it is not possible to define a single level of hypoxaemia that is dangerous to all patients. Some patients with chronic lung disease may be accustomed to living with an SpO_2 of 80%, whereas others with acute organ failure may be harmed by short-term exposure to an SpO_2 of less than 90%. So, the level of hypoxaemia has to be given context not just in severity but also in time and evidence of negative physiological effects. There is no evidence that saturations above normal result in benefits. Rather, hyperoxia can have adverse effects. As a rule of thumb, maintaining SpO_2 greater than 90% in critically ill patients is considered best practice and permits a margin of error.[16, 17] Even though a single-centre study found that for critically ill patients a conservative, compared with a conventional (Fi_{o_2} of at least 0.4, allowing PaO_2 of up to 150 mm Hg), oxygen strategy resulted in a dramatic mortality benefit,[18] a larger multi-centre study did not find any difference between the conservative oxygen therapy (lowest Fi_{o_2} possible was used to achieve the acceptable SaO_2 range of 91%–96%), and usual oxygen therapy (any $SaO_2 > 90\%$ was allowed).[19] However important differences in subgroup of patients were noted (patients with ischaemic hypoxic encephalopathy were found to benefit from conservative oxygen strategy, while patients who had acute brain pathologies other than acute ischaemic hypoxic encephalopathy and patients with sepsis did better with usual care oxygen). Larger studies in this area are underway and results are awaited.[20] Finally, those patients at risk of hypercarbic type II respiratory failure should be managed with a little more caution and their SpO_2 target should be set between 88% and 92%.

Preoxygenation and Apnoeic Oxygenation

Preoxygenation prior to induction of anaesthesia aims to delay desaturation to provide a safe apnoeic period for endotracheal intubation. In patients with normal lungs and ventilatory drive, preoxygenation with 100% oxygen for 3 minutes of tidal breathing, or eight vital capacity breaths over 60 seconds, maximally denitrogenates the FRC to allow maximal oxygen storage in the lung.[21, 22] Many methods of preoxygenation are in common practice. Although the simple method of delivering greater than or equal to 15 L/min O_2 via a tight-fitting semi-rigid face mask with a reservoir bag is described, it can achieve only a Fi_{o_2} between 0.6 and 0.7, as described above, which may be inadequate in the critically ill. Methods of preoxygenation with an Fi_{o_2} of 1.0 include: BVM (with or without PEEP valve), HFNC, Mapleson circuit and NIV.[21, 23-25] NIV may improve preoxygenation when the other methods are >(or are likely to be) ineffective, such as occurs with severe acute and/or chronic hypoxic respiratory failure.[21, 23, 26] A head-up position of 20 degrees or more has been shown to improve the efficacy of preoxygenation, by maximising FRC (and therefore oxygen stores),[21, 23, 27, 28] especially in morbid obesity.[29]

Preoxygenation ends after the patient becomes apnoeic and the oxygen source is removed to allow laryngoscopy and intubation. Continuation of oxygen delivery throughout the apnoeic period (apnoeic oxygenation) has been shown to safely prolong the period of adequate oxygenation, delay the onset of critical desaturation and improve first-pass intubation success.[21], [30-32] Apnoeic oxygenation is likely to provide maximal benefit during prolonged or repeated intubation attempts in an adequately preoxygenated patient with a difficult airway (anticipated or unanticipated). Likewise, it may provide a longer safe apnoea period for the inexperienced intubator to either secure the airway or have a more skilled intubator takeover. However, apnoeic oxygenation is unlikely to benefit the maximally preoxygenated patient who is intubated rapidly by an experienced intubator and may unnecessarily complicate the intubation. In ideal conditions, apnoeic oxygenation can achieve a long delay to desaturation by continually replenishing the denitrogenated FRC with oxygen from the nasopharynx reservoir, limited only by the consequential hypercarbia.[33] Ideal conditions (uncommon in the critically ill) include normal lungs, normal pulmonary circulation, normal DO_2 and an open airway (to allow oxygen flow below the vocal cords during apnoea). The most commonly reported technique for apnoeic oxygenation is the delivery of 15 L/min O_2 via nasal cannulae, commenced on induction (or during preoxygenation).[21], [30-32] The use of HFNC for both preoxygenation and apnoeic oxygenation may offer some advantages due to the ease of use, patient tolerability, improved maintenance of upper airway patency during apnoea and CO_2 washout delaying hypercarbia.[24], [25], [34] Despite a rapid uptake of apnoeic oxygenation practice in the emergency department and pre-hospital settings, its role in the ICU setting is yet to be established due to conflicting studies.[34-37] Indeed, the most recent randomised control trial in the emergency department setting was negative, causing further uncertainty as to when, how and in whom to use apnoeic oxygenation.[38] In addition, studies in all settings are limited by a lack of blinding, no control of preoxygenation techniques or patient position, different methods of apnoeic oxygenation (HFNC vs. nasal cannulae) and variable experience of the intubator.

However, among infants undergoing endotracheal intubation, nasal high-flow therapy during the procedure improved the likelihood of successful intubation on the first attempt without physiological instability in the infant.[39]

Apnoeic oxygenation is also used in clinical brain death testing to demonstrate the absence of a brainstem response to severe hypercarbia (see Chapter 14).

Hazards of Oxygen Therapy

Supply

Medical oxygen supply is a compressed gas. Pipeline supply to the ‘wall’ is usually at 4 bars of pressure (3040 mm Hg). The cylinder supply pressure, when full, is 137 bars (104–120 mm Hg). As such, oxygen as explosion is a risk. Direct administration of oxygen at delivery pressures also carries a real risk of barotrauma to the airway and alveoli, if not governed by an appropriate pressure-limiting valve.

Oxygen also supports combustion. The possibility of sparks in an oxygen-rich environment must be avoided. Patients must not smoke cigarettes when receiving oxygen therapy, even via nasal cannula. Another example is to ensure that oxygen supplies are removed or turned off when defibrillating because a spark can occur in such situations. An ICU fire secondary to an oxygen cylinder explosion has been reported in the literature.[40]

Oxygen Toxicity

Despite being a naturally occurring substance, the use of oxygen in a medical environment should be considered pharmacotherapy. As with all drugs, it has side effects in overdose. There has been a great interest in the potentially toxic effects of oxygen in recent years. The mechanisms underlying oxygen toxicity can primarily be explained by the formation of reactive oxygen species including oxygen free radicals however understanding of the molecular mechanisms underlying hyperoxia is still developing.

As is evident from the previous management of oxygen therapy, there needs to be a limit to the concentrations of oxygen used.[41] There is no apparent benefit in hyperoxia, except in one or two specific settings, with further studies demonstrating the effect of hypoxia as a predictor of mortality, but no strong effect is seen with hyperoxia.[42] Adverse outcomes have also been reported following treatment of postcardiac arrest patients with hyperoxia.[43] These findings also have not been reproduced by further studies, but there is still evidence of a U-shaped mortality curve for PaO_2 in this group of patients.[44] What is more certain is the effect of resuscitation with 100% oxygen in neonates. This has been shown to lead to excess mortality, and air is now the recommended gas to be used in the resuscitation of infants.[45]

Bronchopulmonary Dysplasia

First described in 1967, this is a form of chronic lung disease associated with neonatal ventilation; its pathophysiology includes the same factors as the adult, but with the additional effect of immaturity.[46] The advent of surfactants in the treatment of respiratory distress in the newborn and the addition of maternal steroid therapy to promote pulmonary development have lowered the incidence and reduced the severity of the disease.

Retinopathy of Prematurity

Previously referred to as retrolental fibroplasia, retinopathy of prematurity (ROP) was first described in 1942. It is a vasoproliferative disorder of the eye affecting premature neonates. Similar to the lungs, the completion of development of the retinal vasculature is late in gestation (32–34 weeks).[47] In the 1950s an epidemic of ROP was described and a causal link to uncontrolled oxygen therapy was made.[48] Improved monitoring of oxygen therapy reduced the incidence of ROP but was associated with an increase in perinatal mortality secondary to respiratory failure.[49] Subsequently, and despite good oxygen control, ROP continues to occur. This is now most likely due to the increased survival of increasingly premature low-birthweight infants [50] rather than high PaO_2 alone. This suggests both oxygen- and non–oxygen-related factors. ROP is a biphasic disease in which the relatively hyperoxic environment following delivery initially leads to a slowing or even cessation of retinal vascular development of the premature infant. Additional oxygen may further contribute to this problem by affecting the expression of vascular growth factors. The second phase of the disease is a hypoxic-induced neovascularisation, similar to that seen in diabetic retinopathy. This leads to fibrous scarring with a risk of retinal detachment. How much oxygen is too much remains contentious and further research is required. [51]

Humidification

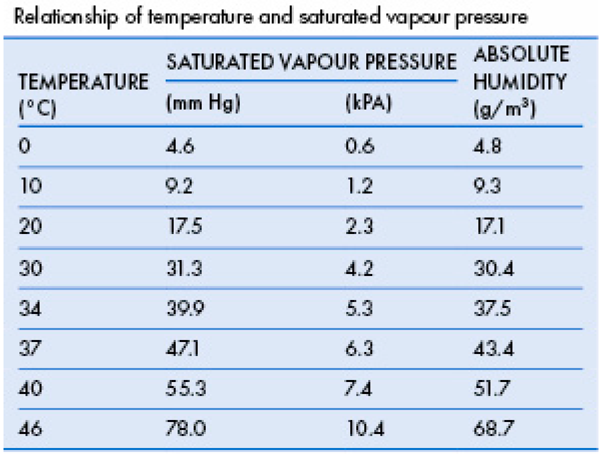
The upper airway normally warms, moistens and filters inspired gas. When these functions are impaired by disease or when the nasopharynx is bypassed by endotracheal intubation, artificial humidification of inspired gases must be provided.

Physical Principles

Humidity, the amount of water vapour in a gas, may be expressed as:

- *absolute humidity (AH):* the total mass of water vapour in a given volume of gas at a given temperature (g/m^3)
- *relative humidity (RH):* the actual mass of water vapour as a percentage of the mass of saturated water vapour, at a given temperature. Saturated water vapour exerts a saturated vapour pressure (SVP). Because the SVP has an exponential relation with temperature (Table 41.1), the addition of further water vapour to the gas can occur only with a rise in temperature
- *partial pressure.*

Table 41.1



Relationship of temperature and saturated vapour pressure

TEMPERATURE (°C)	SATURATED VAPOUR PRESSURE (mm Hg)	(kPA)	ABSOLUTE HUMIDITY (g/m³)
0	4.6	0.6	4.8
10	9.2	1.2	9.3
20	17.5	2.3	17.1
30	31.3	4.2	30.4
34	39.9	5.3	37.5
37	47.1	6.3	43.4
40	55.3	7.4	51.7
46	78.0	10.4	68.7

Physiology

Clearance of surface liquids and particles from the lung depends on beating cilia, airway mucus and transepithelial water flux. Airway mucus is derived from secretions from goblet cells, submucosal glands and Clara cells and from capillary transudate. Conducting airways are lined with pseudostratified, ciliated columnar epithelium and numerous fluid-secreting glands. As the airway descends, the epithelium becomes stratified, and then cuboidal and partially ciliated, with very few secretory glands at the terminal airways. The cilia beat in a watery layer (sol) over which is a viscous mucus layer (gel), and move a superficial layer of mucus from deep within the lung towards the glottis (at a rate of 10 mm/min at 37°C and 100% RH). Both cilia function and mucus composition are influenced by temperature and adequate humidification.

The nasal mucosa has a large surface area with an extensive vascular network that humidifies and warms inhaled gas more effectively than during mouth breathing. Heating and humidification of dry gas are progressive down the airway, with an isothermic saturation boundary (i.e. 100% RH at 37°C or AH of 43 g/m^3) just below the carina.[52] Under resting conditions, approximately 250 mL of water and 1.5 kJ (350 kcal) of energy are lost from the respiratory tract in a day. A proportion (10%–25%) is returned to the mucosa during expiration due to condensation.

The minimal moisture level to maintain ciliary function and mucus clearance is uncertain. Although reproducing an isothermic saturation boundary at the carina may be ideal, it does not seem essential in all situations. Mucus flow is markedly reduced when RH at 37°C falls to less than 75% (AH of 32 g/m ^{3}), and ceases when RH is 50% (AH of 22 g/m ^{3}). [53] This suggests that an AH exceeding 33 g/m ^{3} is needed to maintain normal function. Mucociliary function is also impaired by upper respiratory tract infection, chronic bronchitis, cystic fibrosis, bronchiectasis, immotile cilia syndrome, dehydration, hyperventilation, general anaesthetics, opioids, atropine and exposure to noxious gases. High fractional inspired oxygen concentrations (Fi_{o_2}) may lead to acute tracheobronchitis, with depressed tracheal mucus velocity within 3 hours. [54] Inhaled β_2 -adrenergic agonists increase mucociliary clearance by augmenting ciliary beat frequency, and mucus and water secretion. [55]

Clinical Applications of Humidification

Tracheal Intubation

In the critical care setting, ventilation via a durable artificial airway (endotracheal or tracheostomy tube) generally mandates humidification. As the upper airway is bypassed, RH of inspired gas falls to less than 50% with adverse effects, including [55] :

- increased mucus viscosity
- depressed ciliary function
- cytological damage to the tracheobronchial epithelium, including mucosal ulceration, tracheal inflammation and necrotising tracheobronchitis [56]
- microatelectasis from obstruction of small airways, and reduced surfactant leading to reduced lung compliance
- airway obstruction due to tenacious or inspissated sputum with increased airway resistance.

Metaplasia of the tracheal epithelium occurs over weeks to months in patients with a permanent tracheostomy. These patients do not usually require humidified gas, suggesting that humidification occurs lower down the respiratory tree. Nevertheless, humidification of inspired gas may be needed during an acute respiratory tract infection.

Heat Exchange

The respiratory tract is an important avenue to adjust body temperature by heat exchange. Humidification of gases reduces the fall in body temperature associated with anaesthesia and surgery. [55] Excessive heat from humidification may produce mucosal damage, hyperthermia and overhumidification. [57] However, if the water content is not excessive, mucociliary clearance is unaffected up to temperatures of 42°C. Overhumidification may increase secretions and impair mucociliary clearance and surfactant activity, resulting in atelectasis. [56]

Ideal Humidification

The basic requirements of a humidifier should include the following features [58] :

- the inspired gas is delivered into the trachea at 32–36°C with a water content of 30–43 g/m^3
- the set temperature remains constant and does not fluctuate
- humidification and temperature remain unaffected by a large range of fresh gas flows, especially high flows
- the device is simple to use and to service
- humidification can be provided for air, oxygen or any mixture of inspired gas, including anaesthetic agents
- the humidifier can be used with spontaneous or controlled ventilation
- there are safety mechanisms, with alarms, against overheating, overhydration and electrocution

- the resistance, compliance and dead space characteristics do not adversely affect spontaneous breathing modes
- the sterility of the inspired gas is not compromised.

Methods and Devices

Water-Bath Humidifiers

Inspired gas is passed over or through a water reservoir to achieve humidification. Their efficiency is dependent on ambient temperature and the surface area available for gas vapourisation.

Cold-Water Humidifiers

These units are simple and inexpensive but are inefficient, with a water content of approximately 9 g/m^3 (i.e. approximately 50% RH at ambient temperatures). They are also a potential source of microbiological contamination. Routine use of cold-water humidifiers to deliver oxygen with simple face masks is both unnecessary and at risk of suggesting the gas is adequately humidified.

Hot-Water Humidifiers (Figs. 41.3 and 41.4)

Inspired gas is passed over (blow-by humidifier) or through (bubble or cascade humidifier) a heated-water reservoir. Gas leaving the reservoir theoretically contains high water content. The water-bath temperature is thermostatically controlled (e.g. at 45–60°C) to compensate for cooling along the inspiratory tubing targeting an inspired RH of 100% at 37°C. A heated wire may be sited in the inspiratory tubing to maintain preset gas temperature and humidity. It is commonly believed that hot-water humidifiers do not produce aerosols, but microdroplets (mostly less than 5 µm diameter) have been reported with bubble humidifiers,[59] and this may be a potential source of infection.

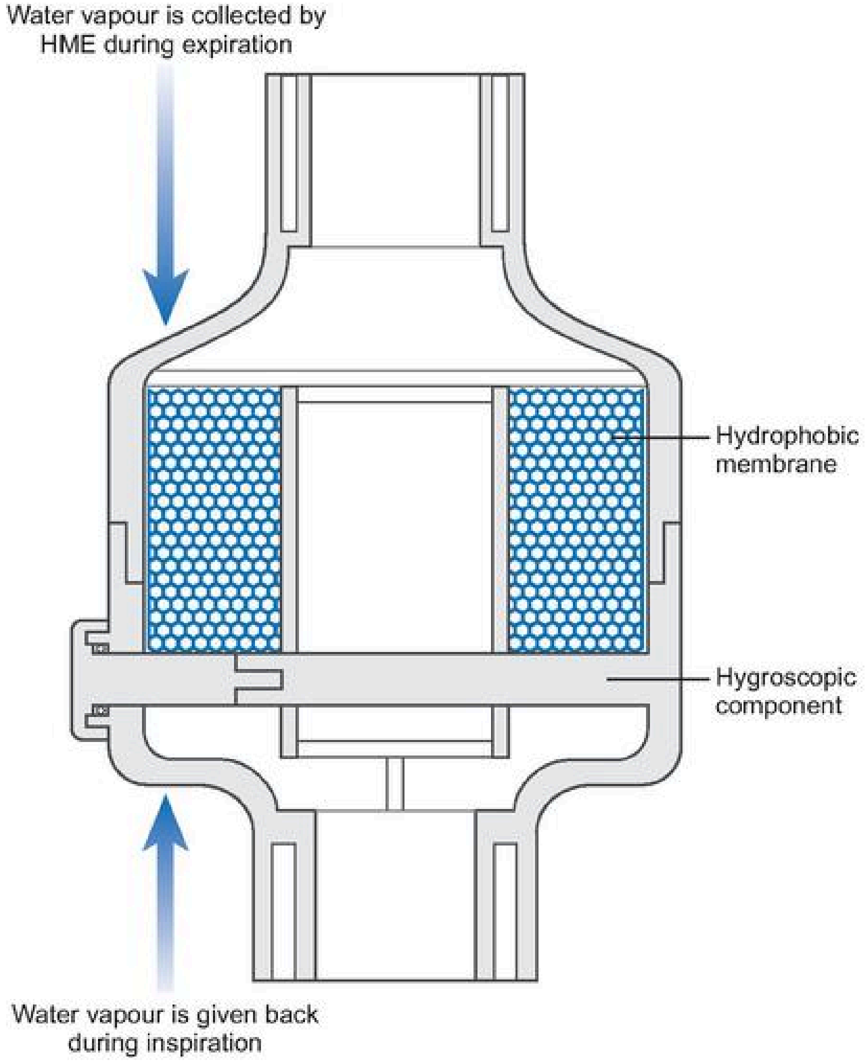
Commonly used blow-by humidifiers incorporate a variety of systems to ensure adequate humidity within set tolerances, as well as alarms and levels of redundancy to prevent harm from excessive heating. Typically, delivery hoses incorporate insulated heating wires to achieve a manual preset inspired temperature. Audible alarms indicate disconnection and variation clinically significant from the set delivery temperature. Heater bases can be protected from overheating by thermostatic control. Disposable humidification chambers are filled manually with water or by a gravity-feed set. To minimise rainout, the chamber outlet can be set at a temperature less than the delivery hose outlet temperature; 2–3°C is usually adequate and does not compromise RH.

Although these humidifiers are often regarded as providing optimal humidification in ventilated patients, their performance is lower than expected both in practice and under optimal conditions in bench studies.[60] Under conditions of high ambient and/or high ventilator output temperature, the inlet temperature to the humidification chamber can be high enough that the heater base operates at a low enough temperature that humidification is impaired, with reduction in inspired water content.[60] The automatic compensation now available on this humidifier helps to compensate for poor performance, which can also be prevented by setting the chamber outlet and hose to 40°C. High-minute ventilation is well tolerated, but a small decrease in water content output has also been found with higher respiratory rates

Heat and Moisture Exchangers

Heat and moisture exchangers (HMEs) are popular ICU humidifiers due to their simplicity and increased efficiency. Modern HMEs are light with a small dead space (30–95 mL) but show great heterogeneity in humidity output, often not matching manufacturer-claimed performance.[61]

Hygroscopic HMEs adsorb moisture onto a foam or paperlike material that is chemically coated (often calcium chloride or lithium chloride), and this tends to increase their efficiency (i.e. AH approximately 30 g/m^3) compared with hydrophobic HMEs (i.e. AH 20–25 g/m^3).[62-67] Such hydrophobic HMEs possess antimicrobial properties and may act as a microbial filter (HME filter or ‘HMEF’). These filters can have efficiencies greater than 99.9%[68] (i.e. less than 23 out of 1 million bacteria will pass through; filters that can exclude all virus particles are not currently available). Modern HMEs include both hydroscopic and hydrophobic properties (Fig. 41.5). However, because nosocomial pneumonia is primarily due to aspiration of oropharyngeal secretions followed by secondary ventilator tubing colonisation, HMEs have not been shown to reduce the frequency of nosocomial pneumonia more than hot-water humidifiers when compared during prolonged ventilation. [68], [69]



Water vapour is collected by HME during expiration

FIG. 41.5 Schematic representation of a heat and moisture exchanger (HME). (Adapted from Al Ashry HS, Modrykamien AM. Humidification during mechanical ventilation in the adult patient . *Biomed Res Int.* 2014;2014:715434.)

The efficiency of older HMEs decreases with time, however, modern HMEs may retain their ability to humidify for prolonged periods with minimal change in resistance (a measure of tube patency and thus adequacy of humidification).[70] In patients undergoing invasive ventilation for a mean duration greater than 1 week, there was no difference in endotracheal tube resistance between HME and active humidification.[71] Similarly, a recent meta-analysis and systematic review found no difference in outcome measures (including endotracheal tube occlusion, mortality and pneumonia) between the modalities.[72], [73] Consequently, HMEs that achieve relatively high AH may be suitable for long-term mechanical ventilation in selected patients, particularly because the majority of reported HME complications (e.g. thick secretions and endotracheal tube occlusion) occur with units of lower humidification levels.[74-76] Nevertheless, HMEs increase dead space and imposed work of breathing and cannot match the humidification offered by hot-water humidifiers, which remain the gold standard, particularly if secretions are thick or bloody or minute ventilation is high[77] or in children and neonates.

Complications of Humidification

Inadequate Humidification

An AH exceeding 30 g/m^3 is recommended in respiratory care.[77] Inadequate humidification is usually a problem only with HMEs. However, with hot-water humidifiers, efficiency is reduced by increasing gas flow rates and rainouts. A decrease of approximately 1°C occurs for each 10 cm of tubing beyond the end of the delivery hose (i.e. the Y-connector and right-angled connector) and should be catered for.

Overhumidification

Overheating malfunction of hot-water humidifiers may cause a rise in core temperature, water intoxication, impaired mucociliary clearance and airway burns.[57]

Imposed Work of Breathing

The work of breathing imposed by a humidifier is primarily resistive work and increases with inspiratory flow rate; the progressive increase in water content of HMEs is also associated with increased resistance.[78] The

Fisher–Paykel humidifier imposes relatively low work compared with a bubble humidifier,[79] and HMEs typically have a resistance of 2.5 cm H_2O/L per second.[65]

Infection

Humidifiers do not appear to be an important factor in nosocomial respiratory tract infection. Although water reservoirs represent a good culture medium for bacteria such as *Pseudomonas* species, it is rare to culture bacteria from humidifiers and is usually preceded by colonisation of the circuit by the patient's own flora within the first 24 hours of use.[80, 81] Indeed the incidence of nosocomial pneumonia is reported to be higher (due to outside contamination) if the circuit is changed frequently (every 24 or 48 hours).[81, 82]

Humidification During Non-Invasive Ventilation

The hygrometric effects of NIV depend upon several factors, including the type of ventilator (conventional versus turbine), patient–ventilator interface, V_T, peak inspiratory flow rates, Fi_{O_2}, degree of mask leak and even ambient room temperature.[83-85]

NIV applied without artificial humidification has been associated with accumulation of dried secretions in the oropharynx with subsequent aspiration, difficult intubation or frank airway obstruction.[86] In healthy volunteers a delivered AH of at least 15 mg H_2O/L was necessary to ensure comfort during NIV.[87] This level is achievable with either passive or active humidification, but in patients with acute respiratory failure, a higher humidity output may be required. Furthermore, the increased dead space and work of breathing associated with HMEs may be undesirable in these situations.[85] Acknowledging the lack of robust data, current guidelines suggest the use of heated humidification over HMEs.[77]

Humidification for Oxygen Therapy During Spontaneous Breathing

Despite the ubiquity of oxygen therapy, there is no evidence to guide the addition of humidification for spontaneously breathing patients. No discrete oxygen flow rate or duration of exposure mandates artificial humidification. An exception is HFNC which is becoming increasingly applied both within and outside the critical care environment. Humidification is an integral component of this therapy with fresh gas flow rates typically set at 30–60 L/min [88], [89] However, even with simpler devices providing flow rates of ≤15 L/min, patient discomfort is ameliorated with the use of heated humidification compared with bubble humidifiers or no artificial humidification at all. [90], [91] It is unknown to what extent patient discomfort signals inadequate humidification and the potential for complications such as deranged mucociliary transport or increased airway resistance.

Inhalation Therapy

Therapeutic aerosols are particles suspended in gas that are inhaled and deposited within the respiratory tract. Numerous factors, including particle size, inertia and physical nature, gravity, volume and pattern of ventilation, temperature and humidity, airway geometry, lung disease and the delivery system, alter aerosol deposition. In general, particles of diameter 40 µm deposit in the upper airway, those of 8–15 µm deposit in bronchi and bronchioles, those of 3–5 µm deposit in peripheral conducting airways and those of 0.8–3.0 µm settle in lung parenchyma. Optimal particle size will depend on the clinical indication and agent used. Obviously, if an HME with filtration characteristics is being used, the aerosol needs to be delivered proximal to the filter. Clinical efficacy of newer HME designs incorporating the facility for aerosol delivery remains to be quantified. [92]

Aerosol Delivery

Therapeutic aerosols may be delivered by nebuliser (jet, ultrasonic or VMN), pressurised metered-dose inhaler (pMDI) or dry-powdered inhaler (DPI). Although each of these methods tends to be less efficient in ventilated patients, provided that care is taken to optimise their performance, each can provide equivalent clinical effect.

Nebulisers

The most common jet nebulisers are sidestream nebulisers. These use an extrinsic gas flow through a narrow orifice, to create a pressure gradient that draws the drug mixture from a liquid reservoir (i.e. Bernoulli principle; Fig. 41.6). The gas is then directed at a baffle to reduce the mean particle size. This extrinsic gas flow (usually 3–10 L/min) alters the effective Fi_{o2}, adds to the inspiratory flow and may increase patient tidal volume unless the ventilator automatically compensates or the preset tidal volume is adjusted. Furthermore, this additional gas flow may impair ventilator triggering because it may prevent the development of a negative pressure or necessary reduction in continuous flow needed. Mainstream nebulisers use inspiratory gas flow to actuate nebulisation. These are commonly large-volume water nebulisers that entrain air to achieve fresh gas flow rates of 20–30 L/min.

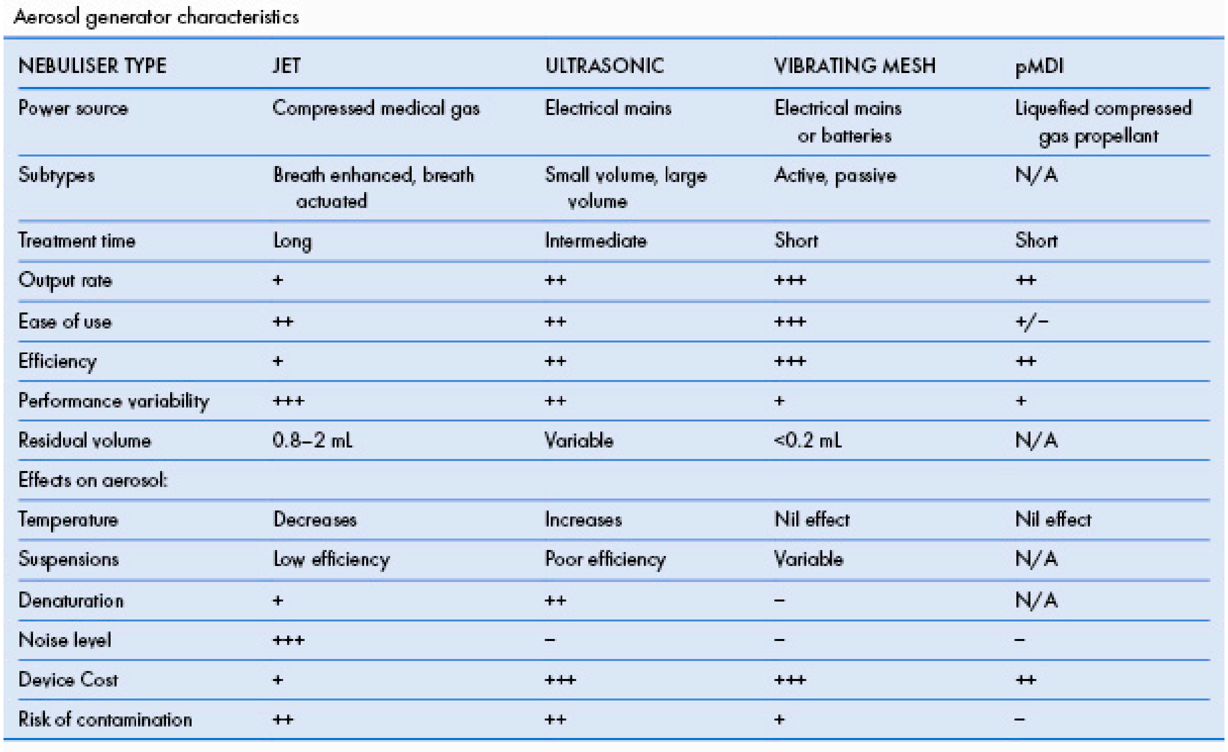
The diagram presents two types of nebulisers for drug delivery. Part A on the left depicts a jet nebuliser. It includes a reservoir labelled fresh source at the top, connected to a patient interface. Below the reservoir, a section labelled drug solution contains liquid. A compressed gas source connects to the drug solution through a jet, with baffles and a venturi mechanism labelled on the left side. A power supply control unit connects to the bottom. Part B on the right depicts an ultrasonic nebuliser and a vibration mesh nebuliser. The ultrasonic nebuliser has a reservoir labelled drug solution at the top, with acoustic waves and a piezo-electric transducer below, connected to a power supply. The vibration mesh nebuliser, depicted in a magnified view, has a piezo-electric actuator mesh labelled at the bottom, with conical apertures that act as a micropump to form fine droplets. An aerosol connects to the patient interface at the top. Labels indicate the flow of aerosol to the patient in both parts.

FIG. 41.6 Schematic representation of nebuliser design (A) jet nebuliser, (B) ultrasonic nebuliser and (C) VMN. (From Yeo LY, Friend JR, McIntosh MP, et al. Ultrasonic nebulisation platforms for pulmonary drug delivery . *Expert Opin Drug Deliv.* 2010;7(6):663–679.)

Ultrasonic nebulisers use high-frequency sound waves (typically 1 MHz) to create an aerosol above a liquid reservoir, to produce small uniform droplets (<5 μm) and a high mist density (i.e. 100–200 g/m^3). Tidal volume is not altered; however, ultrasonic nebulisers may cause overhydration and increased airway resistance. Further drawbacks in the critical care setting include size, poor battery life and the potential for drug inactivation (protein denaturation) by ultrasonic waves and heating.[93, 94]

More recent nebuliser designs have used a vibrating mesh (VMN) or plate. Medication in solution or suspension is forced through multiple apertures in the mesh or plate to produce an aerosol. A variety of VMNs are commercially available; common features include aerosol generation with high fine-particle fraction and overall higher drug output with minimal residual volume compared with jet nebulisers; additional benefits over ultrasonic types are the lack of heating effect or potential for drug degradation.[93] A comparison of the features of aerosol generators is shown in Table 41.2 .[95]

Table 41.2



Aerosol generator characteristics

NEBULISER TYPE	JET	ULTRASONIC	VIBRATING MESH	pMDI
Power source	Compressed medical gas	Electrical mains	Electrical mains or batteries	Liquefied compressed gas propellant
Subtypes	Breath enhanced, breath actuated	Small volume, large volume	Active, passive	N/A
Treatment time	Long	Intermediate	Short	Short
Output rate	+	++	+++	++
Ease of use	++	++	+++	+/−
Efficiency	+	++	+++	++
Performance variability	+++	++	+	+
Residual volume	0.8–2 mL	Variable	<0.2 mL	N/A
Effects on aerosol:				
Temperature	Decreases	Increases	Nil effect	Nil effect
Suspensions	Low efficiency	Poor efficiency	Variable	N/A

Noise level	+++	−	−	−
Device Cost	+	+++	+++	++
Risk of contamination	++	++	+	−

pMDI , Pressurised metered-dose inhaler; *N/A,* not applicable.

See references 94, 97.

Metered-Dose Inhalers

pMDIs contain drug in ethanolic solution with a hydrofluoroalkane (HFA) propellant, allowing a relatively fixed volume (i.e. dose) to be delivered with each actuation (e.g. 100 µg for salbutamol and 20 µg for ipratropium).[93, 96] Aerosol delivery is approximately 4–6% in ventilated adults but increases to 11% when a spacer chamber is used, which is similar to optimal no-spacer values reported in the ambulant population.[97]

Dry-Powdered Inhalers

DPIs are commonly used in ambulant practice. Their use is not recommended in patients undergoing mechanical ventilation because they are breath actuated (requiring inspiratory flow rates close to 60 L/min) and, moreover, circuit humidification can cause powder clumping with impeded aerosol formation.[98]

Configuring Aerosol Delivery During Different Modes of Ventilatory Support

Invasive Mechanical Ventilation

Without preference, consensus guidelines recommend a choice of either VMNs or pMDIs with spacer for aerosol delivery during invasive ventilation.[99] Continuous jet nebulisers are less favoured on account of numerous drawbacks as described above.

For all types of nebuliser design, aerosol deposition is highly variable, with significant rainout in the ventilatory circuit, endotracheal tube and large conducting airways. In a bench study, delivery ranged from 6% of nebuliser charge to 37% depending upon humidification and breath activation; parallel in vivo data were similar but found a 20-fold difference in drug delivery.[100] Numerous factors have been shown to improve aerosol deposition, but only some of these are commonly practised (Table 41.3).[101], [102] For example, although heating and humidification reduce aerosol deposition by approximately 50% due to an increase in both droplet size and rainout, regular circuit disconnection and exclusion of humidification prior to nebulisation are not practical and not recommended.[103] The position of the aerosol generator within the ventilator circuit also affects aerosol delivery, and is particularly relevant in the setting of continuous ventilator bias-flow. In this context, VMN, ultrasonic and jet nebulisers are most efficient when placed in the inspiratory limb of the circuit, away from the Y-piece and closer to the ventilator inspiratory port,[104] allowing the ventilator tubing to act as a reservoir or aerosol-holding chamber. Inspiratory activation of the nebuliser increases deposition by twofold and threefold under dry and humidified conditions, respectively[94]; use of a large chamber fill, tidal volume of 500 mL or more and minimisation of turbulent inspiratory flow (low-flow rate, prolonged inspiratory time) also augment aerosol delivery. [91] For pMDIs, similar conditions such as the inspiratory limb position, inspiratory activation and minimisation of turbulence by lowering inspiratory flow rate and prolonging inspiratory time will increase aerosol delivery. It is important to avoid the use of an elbow adapter because this has been associated with dramatic reductions in aerosol delivery and efficacy.

Table 41.3

Factors favouring effective aerosol delivery

Ventilator settings	Lower flow rate (30–50 L/min ideal) Long inspiratory time Higher PEEP Larger tidal volume (≥500 mL) Lower bias-flow Breath-actuated mechanism
Circuit factors	Larger endotracheal or tracheostomy tube better Delivery *without* humidification is better (i.e. remove HME; turn off heated humidification 10 min prior to therapy) Preferred positioning of aerosol generator (during invasive mechanical ventilation): VMN, USN, pMDI: inspiratory limb, 15 cm from Y-piece Jet nebuliser: inspiratory limb, 15 cm from ventilator outlet Preferred positioning of aerosol generator (during NIV): Close to patient interface Driving gas: potentially increased peripheral deposition with heliox
Drug factors	Particle size 2–5 µm more likely to deposit further in respiratory tract
Patient factors	Ensure clear and patent airway
Type of aerosol generator	See Table 41.2 Nebulisers allow for continuous and potentially greater cumulative aerosol delivery For pMDIs, shake and warm to hand temperature prior to use

HME , Heat and moisture exchanger; *NIV* , non-invasive ventilation; *PEEP,* positive end-expiratory pressure; *pMDI* , pressurised metered-dose inhaler; *USN* , ultrasonic nebuliser; *VMN* , vibrating mesh nebuliser.

See references 93, 97, 99, 100.

Non-Invasive Ventilation

There is no requirement to interrupt NIV to administer inhaled bronchodilator therapy. Both nebulisers and pMDIs appear effective during NIV, although in this context, ultrasonic nebulisers are associated with the greatest drug loss [97,105-107] When utilising dual-limb circuits, nebulisers should be placed as per invasive ventilation (i.e. near the inspiratory outlet). However, if using a single-limb configuration, the optimal positioning of the aerosol-generating device appears to be closer to the patient interface and distanced from the ventilator (i.e. between the mask and the leak port). [103]

High-Flow Nasal Cannulae

Aerosol drug delivery during NHFC can result in significant amounts of drug loss both through impaction in the circuit and directly to the atmosphere. [106] Nonetheless, the efficiency of aerosol delivery is similar to that when using nebulisers with a mask or mouthpiece. VMN are the preferred type nebuliser, [108,109] providing 2–3 fold higher delivery than jet nebulisers without the associated effects on flow or Fi_{o_2} . pMDIs can also be used in line with NHFC, with a spacer placed close to the nasal cannulae.

Infection Control Considerations

The potential risk associated with nebulisation for transmission of pathogens was highlighted in the COVID-19 pandemic. In the health care setting, fugitive aerosols can originate from nebulisers by design (therapeutic aerosols) or from the patient (bioaerosols). In the context of infection control, the designation of nebulisation as an ‘aerosol-generating procedure’ and the quantification of any associated risk remains controversial.[110-112] The World Health Organisation maintains a position of ambiguity, citing a lack of quality evidence.[113] Adherence to local policies and guidelines is recommended. Particularly in the critical care environment, a cautious approach is advised, acknowledging that patients with known COVID-19 or other highly transmissible infections are likely to be subject to airborne precautions in any case.

Clinical Applications of Inhalation Therapy

Humidification

Humidifiers produce gas with a water content dictated by temperature and water vapour pressure, whereas nebulisers produce gas with a water content determined by the aerosol content. The latter can provide water to the respiratory tract, particularly if the water reservoir is heated to increase mist density. However, the risk of infection is increased because droplets can carry bacteria to the alveoli. Consequently, only sterile water should be used to fill the reservoir, and all units should be regularly changed and sterilised.

Mucolytics

N -acetylcysteine and other thiol derivatives such as carbocysteine and erdosteine can liquefy mucus by directly severing disulfide bridges in mucoproteins and DNA. In outpatients with chronic obstructive pulmonary disease (COPD), particularly in those not receiving inhaled corticosteroids, these mucolytic agents result in a very modest reduction in COPD exacerbations and improved quality of life.[114], [115] Notably, these clinical trials have used oral formulations because inhalational administration can induce bronchospasm and for the generic ICU population of invasively ventilated patients, there is no empirical evidence to support improved outcomes,[116], [117] Nonetheless, the use of these thiol derivatives is common in this patient cohort; a pragmatic, randomised control of systemic carbocysteine is currently underway.[118] Recombinant human DNase (dornase alfa) has an established evidence base for utility in cystic fibrosis[119], [120]; the onset of the COVID-19 pandemic has prompted renewed interest in this agent. With small case series and larger trials ongoing, DNase may act beneficially by impeding neutrophil extracellular trap formation.[121], [122]

Sputum Induction

Hypertonic nebulised saline (typically as 3% or greater solution) is effective in sputum induction for diagnosing *Pneumocystis jiroveci* pneumonia in patients with acquired immunodeficiency syndrome. The need for bronchoscopy can be obviated,[123] with specificity of sputum induction approaching 100% and sensitivity of at least 55%.[124] Similar benefits are noted for the diagnosis of pulmonary tuberculosis.[125] Sputum induction has been used to diagnose a number of other infections and appears to be safe in patients with severe airflow limitation.[126] In any case the procedure should be performed by trained personnel with appropriate personal and environmental protection.

Additionally, nebulised hypertonic saline can be delivered with therapeutic intent as a mucoactive agent; in this context, the putative action is as an expectorant rather than as a direct muco-regulatory agent.[127] Akin to the status of carbocysteine, empiric evidence from controlled trials is in progress.[118]

Bronchodilator Therapy

Optimal aerosol delivery and bronchodilator response are extremely important in critically ill patients with severe airflow limitation; this can be achieved using either a nebuliser or pMDI technique, provided that care is taken to optimise performance. For mechanically ventilated patients, there is currently no evidence to recommend one device type.[128] Efficacy of pMDI administration is improved by the use of a spacer with actuation synchronised with the onset of inspiration.[93] The response can be judged clinically, and in ventilated patients monitored by changes in peak-to-plateau airway pressure gradient, calculated airway resistance and intrinsic PEEP. Numerous studies show effective bronchodilatation with β_2-agonists and anticholinergic agents such as ipratropium in ventilated patients, and their combination is more effective than a single agent alone. For non-obstructive pulmonary conditions, including acute respiratory distress syndrome (ARDS), routine use of inhaled bronchodilators is not beneficial and has been associated with increased harm.[129, 130]

Bronchodilator dosing

Standard doses of salbutamol for acute asthma are 2.5–5 mg administered by a nebuliser or 4–6 puffs of a pMDI (400–600 µg), but the bronchodilator response can be shorter lasting than in ambulatory subjects. Consequently, dosing should be 3–4 hourly. Ipatropium is usually administered as 0.5 mg by a nebuliser or four puffs (80 µg) of a pMDI. Higher or more frequent drug dosing is often effective when there is severe, reversible airflow obstruction, and continuous nebulisation of a β_2-agonist may be used in acute severe asthma until there has been a clinical response. If the patient is moribund with minimal ventilation or is unable to tolerate nebulisation, parenteral administration should be considered; however, under most circumstances, there is no particular benefit with this route.[131]

Inhaled Corticosteroids

Inhaled corticosteroids are recommended in moderate persistent asthma[132] and in COPD when associated with frequent exacerbations or persistent symptoms despite the use of long-acting inhaled bronchodilators.[133] However, in acute episodes of these conditions, inhalational delivery does not preclude the need for systemic corticosteroid therapy. Small-particle inhaled corticosteroids offer the theoretical benefit of improved total and peripheral lung distribution.[134] HFA-propelled ciclesonide, flunisolide and beclomethasone dipropionate all have mass median aerodynamic diameters (particle size) of less than 2 µm.[134, 135] There is scarce data to suggest significant clinical benefits over the larger-particle formulations with evidence in mechanically ventilated patients yet to be demonstrated.

Delivery of Antibiotics and Antiviral Agents

With clinical experience spanning many decades, aerosolised antibiotics have entered a renaissance. International surveys suggest that inhaled antibiotic use is common in ICU patients undergoing mechanical ventilation,[136] and several reviews of the topic have recently been published.[137-145] The main driver of this renewed interest has been the emergence of multidrug-resistant (MDR) pathogens. Albeit contentious, pulmonary delivery of antibiotics has theoretical benefits of achieving high tissue concentration at the site of infection while minimising systemic adverse effects. A further consideration is that in patients with purulent secretions, antibiotic concentrations may need to exceed 10–25 times the minimum inhibitory concentration to be effective.[146]

The argument for inhaled antibiotics is most appealing for aminoglycosides and polymixins. These antibiotic classes exhibit concentration-dependent bactericidal effects, have significant systemic toxicities and are perhaps the best-studied agents in this context. In humans, gentamicin by conventional intravenous dosing has been shown to reach only subinhibitory concentrations in the alveolar lining fluid.[147] In animal models of bronchopneumonia, inhaled amikacin achieved 3- to 30-time increases in lung tissue concentrations and better sterilisation of the lung compared with intravenous administration.[148]

Inhaled tobramycin is recommended in patients with cystic fibrosis and chronic *Pseudomonas aeruginosa* infection, due to its association with improvement in several clinically relevant endpoints, such as improved lung function per spirometry, improved quality of life and decreased exacerbation frequency and hospitalisation rates.[149-151] Similar benefit has been demonstrated with aztreonam, with lesser evidence for colistin.[139]

For the intensivist, the focus is the role of inhaled antibiotics in treating ventilator-associated pneumonia (VAP) and ventilator-associated tracheitis (VAT). Improved clinical cure rates have been found with nebulised gentamicin[152] and colistin.[141], [153] The presumption of emerging bacterial resistance with increased aerosolised antibiotic use, akin to the known risk with systemic delivery, is not confirmed by the available data. Paradoxically, emergence of resistance may be reduced via higher pathogen eradication rates, earlier intervention in treating VAT and reduced exposure to systemic therapy.[154]

Extending this argument further, in line with the ‘transcolonisation’ hypothesis of VAP pathogenesis,[155] a recent trial examined the impact of nebulised amikacin administered universally to ICU patients invasively ventilated for greater than 72 hours. With this pre-emptive or prophylactic strategy, the incidence of subsequent VAP was significantly reduced, but the study was underpowered to detect any difference in other endpoints such as ICU length of stay ventilator-free days. [156] However, the data suffers from methodological heterogeneity and small patient numbers. The described dosing in VAP (total daily amount) varies widely amongst studies: gentamcin (240–320 mg), colistin (75–300 mg) and amikacin (200–1200 mg). Moreover, there is little consistency in factors known to affect aerosol delivery, such as aerosol generator type or ventilator parameters. Two systematic reviews of inhaled antibiotics in VAP (with or without combined parenteral antibiotics) have not shown definitive benefit. [138, 140] Likewise, two recent randomised trials failed to show any benefit of inhaled antibiotics as adjuncts to parenteral therapy for VAP. [157, 158] A pragmatic approach is taken by the Infectious Diseases Society of America and American Thoracic Society Guidelines, which state that for patients with VAP due to MDR Gram-negative bacilli (susceptible only to aminoglycosides or polymyxins) both inhaled and systemic antibiotics are recommended, rather than systemic antibiotics alone. [159] It is also considered reasonable to add inhaled antibiotics for patients deteriorating despite appropriate parenteral therapy, even if the organism is not identified as MDR. [159] This rationale places preferential weighting on the potential benefits in these high-risk patient populations against any potential adverse effects. The same guidelines do not extend this recommendation to the treatment of VAT. [159] It should be noted that rarely, and ironically, even systemic adverse effects may result from inhaled administration. [142]

Other antimicrobials that have been safely nebulised include vancomycin, ceftazidime, fluoroquinolones and pentamidine. Inhaled amphotericin B may have a role in treating and preventing invasive fungal disease in select immunosuppressed patients (such as those with haematological malignancy or lung transplantation) but may result in bronchospasm. Aerosolised ribavirin has limited evidence of benefit for respiratory syncytial virus infection [160, 161] but may have a significant role specifically in adult haematopoietic stem cell transplant recipients. [162, 163] Ribavirin deposition in the circuit may cause valve malfunction, and concerns of teratogenicity in health care personnel have dictated its use with care.[161] Inhaled zanamivir is associated with reduced duration of illness with influenza infections but can also cause bronchospasm.[164] However, the inhalational powder is not recommended for nebulisation or use in mechanically ventilated patients due to the potential for obstruction of the ventilator expiratory filter.[165]

The development of polymeric nanoparticles and related derivatives may improve antibacterial efficacy by promoting prolonged contact with culprit bacteria and penetration into biofilms.[143, 145] Finally, the promise of inhaled biologically active medications, such as bacteriophages, monoclonal antibodies and immunomodulators remains to be tested.[166, 167]

Surfactant Therapy

Surfactant preparations have been delivered by instillation and as an aerosol in neonates with respiratory distress syndrome and in adults with ARDS. Aerosolised surfactants can theoretically achieve more uniform distribution and avoid problems of instilling liquid into injured lungs. However, large amounts are needed for lung deposition, and preferential distribution occurs to less-damaged lung areas that receive better ventilation.[168] Unfortunately, clinical studies of exogenous surfactants in adult ARDS have not shown any mortality benefit and may be associated with excess harm.[169, 170]

Inhaled Nitric Oxide and Prostanoids (see Chapter 37 on Acute Respiratory Distress Syndrome)

Inhaled Helium Mixtures

Helium is 7.2 and 8 times less dense than air and oxygen, respectively. This property is useful in the setting of increased airway resistance because less turbulent and more efficient laminar flow is encouraged. Therefore, albeit an inert gas without any direct anatomical effect, helium can improve dynamic respiratory mechanics and reduce work of breathing. Effect size relates to the relative helium concentration; in practice at least 60%–70% helium is required, limiting applicability to patients able to tolerate Fi_{O_2} of

30%–40%. Helium–oxygen mixtures (heliox) potentially have a role in managing obstructive disease of both the upper and lower airways. However, the clinical use of heliox remains controversial and without evidence-based guidelines. In patients with COPD exacerbations requiring NIV, heliox has not been proven to reduce the NIV failure or the duration of NIV.[171], [172] Similarly, there is no definitive evidence that heliox improves outcomes in asthma exacerbations, but its use can be considered in mechanically ventilated patients with severe asthma.[89] In a recent small study of patients with severe airflow limitation, heliox did reduce peak inspiratory airway pressure but had no effect on markers of dynamic hyperinflation (plateau pressure and total PEEP). It should be noted that heliox, as a driving gas, will influence the delivery of other inhaled agents in a ventilator circuit and also aerosols via nebulisers. Heliox may improve particle distribution to the peripheral small airways, perhaps as a function of reduced turbulence.[173] There is some evidence that bronchodilators driven by heliox (vs. oxygen) result in improved clinical outcomes.[174]

Mechanical ventilator support

Andrew Bersten and Shailesh Bihari

Mechanical ventilation for acute respiratory failure (ARF) is now routine in the intensive care unit (ICU). The 1952 Copenhagen polio epidemic introduced the notion of organised areas for the provision of positive-pressure ventilation, [1] which was usually applied through a tracheostomy that had been inserted to allow suction of secretions. However, methods of ventilatory assistance without intubation had proliferated prior to the polio epidemic (both negative-pressure chest wall devices and positive-pressure face-mask devices), and current trends are to an increased use of non-invasive ventilation (NIV) in patients with respiratory failure. [2]

Almost all of the ventilatory modes that are conventionally applied during *intubated* ventilation (IV) can be applied *non-invasively* ; however, IV remains the primary mode of respiratory assistance in critically ill patients. There is also an increasing number of patients receiving chronic ventilatory assistance, but, since the majority of these use chronic NIV, this chapter is primarily directed at intubated mechanical ventilation for both ARF and acute-on-chronic respiratory failure.

A Physiological Approach

During normal spontaneous breathing, contraction of the respiratory muscles overcomes both the elastic recoil and resistance of the respiratory system (lung and chest wall). A fall in regional pleural pressure results in alveolar inflation due to the resultant pressure gradient. Expiration is usually passive, but the expiratory muscles may assist the elastic recoil of the respiratory system.

The driving force for ventilation under normal circumstances is provided by the respiratory muscles.[3] During spontaneous breathing, as the thoracic cage expands, this causes a decrease in intrathoracic pressure (pleural pressure) relative to the atmosphere (in normal conditions approximately 2 mm Hg is sufficient to expand the thoracic cage by 400 mL).[4] Because the lungs are connected in series with the thoracic cage, their volume is expanded to a nearly equal extent. The force that distends the lung is the pressure difference between the alveoli and pleural cavity; the transpulmonary pressure.

During positive-pressure mechanical ventilation, the rules are exactly the same, with the exception that the force provided by the ventilator substitutes this driving force, and the force is applied to the lung parenchyma and not to the chest wall. The airway pressure at plateau during an end-inspiratory pause (in quasi-static conditions), is spent first to expand the lung and second to expand the chest wall.[3] During spontaneous breathing, pleural pressure is negative (facilitating venous return), whereas during mechanical ventilation it is positive (impairing venous return).

The work (W) performed by the respiratory muscles (W_{mus}) can be measured from the relationship between pressure (P) and volume (V), and partitioned into elastic (W_{el}) and resistive (W_{res}) work:

$$W_{\mathrm{mus}} = W_{\mathrm{el}} + W_{\mathrm{res}} \tag{42.1}$$

Inertial work is negligible, and usually ignored; furthermore, Eq. (42.1) does not explicitly describe the elastic work required to initiate inspiration when intrinsic PEEP (PEEP $_{\mathrm{i}}$) is present.

Because volume is constant in Eq. (42.1) , it can be simplified to:

$$P_{\text{mus}} = P_{\text{el}} + P_{\text{res}} \quad \textbf{(42.2)}$$

It follows that during positive-pressure ventilatory assistance, where P_{ao} is the ventilatory pressure applied to the airway:

$$P_{\text{ao}} + P_{\text{mus}} = P_{\text{el}} + P_{\text{res}} \quad \textbf{(42.3)}$$

and that when the work is solely applied by the ventilator with no respiratory muscle contraction (controlled mechanical ventilation [CMV]):

$$P_{\text{ao}} = P_{\text{el}} + P_{\text{res}} \quad \textbf{(42.4)}$$

This nomenclature allows physiological discussion of the different ventilatory modes from controlled ventilation to spontaneous, unassisted ventilation and introduces the equation of motion that is used in the estimation of respiratory mechanics:

$$P_{\text{ao}} = E_{\text{rs}} \cdot V + R_{\text{rs}} \cdot \dot{V} + P_{\text{o}} \quad \textbf{(42.5)}$$

where E_{rs} is the respiratory system (lung and chest wall) elastance (the inverse of compliance), R_{rs} is the respiratory system resistance, $\dot{V}$ is the gas flow rate, and P_{o} is the total PEEP (the sum of extrinsic PEEP [PEEP$_{\text{e}}$] and PEEP$_{\text{i}}$). PEEP$_{\text{i}}$ imposes a threshold load – additional elastic work, as inspiratory muscle contraction must occur without $\dot{V}$ until P_{ao} falls below atmospheric pressure (see below, patient–ventilator interaction).

Transpulmonary Pressure

As the same driving force is applied to the whole respiratory system (lung and chest wall), the resulting transpulmonary pressure may be extremely variable. If the lung is relatively ‘stiff’ and the chest wall is relatively ‘soft’ (e.g. during pulmonary fibrosis or ARDS of pulmonary origin), a greater fraction of the airway plateau pressure is spent to distend the lung (high transpulmonary pressure). In contrast, if the lung is relatively soft but the chest wall is relatively stiff (e.g. in the presence of an abdominal disease, chest binder or severe obesity), most of the driving force is spent to move the chest wall (high pleural pressure).[3]

Force-Bearing Structure of Lung Parenchyma

The transpulmonary pressure is applied to the extracellular matrix which is the force-bearing structure of lung parenchyma and constitutes the lung skeleton.[5] The lung skeleton is a complex and metabolically active structure that includes a network of elastin, collagen and proteoglycans. All these molecules are involved in determining the mechanical characteristics of the respiratory system. The elastin may be considered an elastic spring, whereas the inextensible collagen, which is folded at end expiration and completely unfolded at a lung volume equal to total lung capacity, acts as a stop-length fibre.[6,7] The proteoglycans stabilise the collagen-elastin network, at low and medium lung volumes contributing to lung elasticity and alveolar stability.[8]

The epithelial and endothelial cells do not directly bear the applied forces because they are anchored to the extracellular matrix by a series of structural proteins (integrins), which are connected to the cytoskeleton. However, during lung expansion, the epithelial and the endothelial cells modify their shape.[3]

Mechanical ventilation-induced cellular deformation activates a series of mechanosensors with the production of several inflammatory mediators, such as cytokines, metalloproteinases, leukotrienes and interleukins. [9-13]

Concept of Stress and Strain

Stress is the applied force, and strain is the linear deformation of material. In the whole lung, the rough approximation of stress is the transpulmonary pressure, whereas the approximation of the average strain is the change in volume relative to the lung resting volume. The ratio between alveolar stress and strain is defined as lung-specific elastance. [3] In acute respiratory distress syndrome (ARDS), lung-specific elastance is close to normal, reinforcing the concept of the baby lung (lung is small and not stiff). [14] , [15]

Extrapulmonary effects of mechanical ventilation

Cardiac Effects

Changes in intrathoracic pressure from positive-pressure ventilation in addition to affecting ventilation and ventilation distribution, also affect cardiovascular function. [16] , [17] An increase in the intrathoracic pressure will decrease the right ventricular filling. In addition, this can also increase the right ventricular afterload, further compromising cardiac output, in part as right ventricular dilation can lead to septal shift compromising left ventricular filling. Conversely, elevations in intrathoracic pressure can improve left ventricular function because of an effective reduction in the afterload. [17] The sudden release of intrathoracic pressure (e.g. during a ventilator disconnect or spontaneous breathing trial) can sometimes precipitate flash pulmonary oedema because of the acute increase in afterload coupled with increased venous return [18] and corresponding effects of ventricular interdependence. [19]

Lung Perfusion

Intrathoracic pressures can also influence the distribution of lung perfusion. The relationship between alveolar and perfusion pressures in the three-zone lung model can be used to help explain this. [20] Specifically, the supine human lung is generally in zone 3 (vascular distention) state. However, as the intra-alveolar pressures rise, the zone 2 and zone 1 regions can appear, creating high V/Q units. Hence, increases in dead space (i.e. zone 1 of the lung) can result as a consequence of high ventilatory pressures or in the setting of high PEEP. [21]

Other effects

Mechanical ventilation with positive airway pressure has an inhibitory effect on the kidney, which results in a decrease in renal water and sodium excretion. Physical, hormonal and nervous factors are involved in this process. [22] Mechanical ventilation can also increase intra-cranial pressure and decrease cerebral perfusion pressure because of the increased intrathoracic pressure associated with mechanical ventilation. Positive end-expiratory pressure (PEEP) has the potential of decreasing mean arterial pressure and venous return. A decrease in venous return increases intra-cranial pressure and a decrease in mean arterial pressure decreases cerebral perfusion pressure. [23]

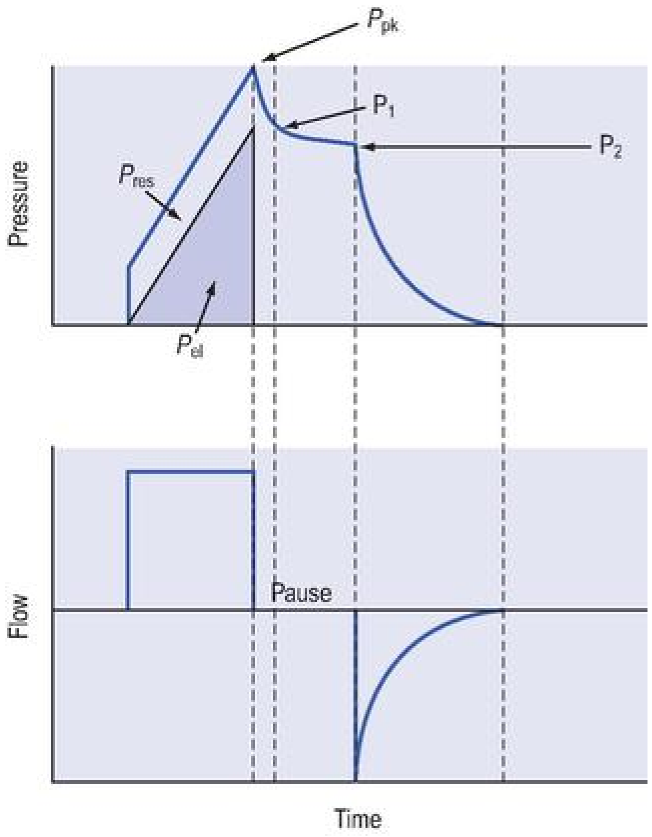
Modes of ventilation

Controlled Mechanical Ventilation

The simplest form of positive-pressure breath occurs in a relaxed subject, and the ventilator provides a constant gas flow during inspiration

$$\mathrm{P}_{ao} = E_{rs} V + R_{rs} \overset{+}{V} Po$$

The volume delivered will depend upon the inspiratory time (T_i), and P_{ao} during inspiration will reflect E_{rs} and R_{rs} (Fig. 42.1). Expiration is a passive, and usually exponential, decline in volume to the relaxation volume of the respiratory system, also termed the functional residual capacity (FRC).



The two graphs display pressure-time and flow-time waveforms during mechanical ventilation. The top panel plots pressure against time, which indicates peak pressure, resistive pressure, elastic pressure, plateau pressure, and end pressure. The curve rises sharply during inspiration, plateaus during an inspiratory pause, and gradually falls during expiration. The bottom panel plots flow against time, which shows a square wave inspiratory flow that stops abruptly during the pause phase, followed by a decaying expiratory flow curve. Vertical dashed lines mark the transition points between phases, with Pause labelled in the inspiratory hold phase. The graph visually represents the components of airway pressure during volume-controlled ventilation.

FIG. 42.1 Schematic diagram of a volume-controlled breath with constant inspiratory flow. A period of no inspiratory gas flow has been interposed before expiration (pause) to illustrate dissipation of lung resistance as airways resistance (fall from P_{pk} to P_1) and tissue resistance (fall from P_1 to P_2). The inspiratory pressure due to the elastic properties of the respiratory system is illustrated in the top panel as the filled area (P_{el}), and the lung resistive pressure is labelled as P_{res}. (See text for more detail.)

CMV is the most basic form of mechanical ventilation; however, it is extremely useful, and still commonly used. Preset minute ventilation is made up of a fixed respiratory rate (f) and tidal volume (V_T). Provided that there are no large variations in alveolar dead space, this maintains preset alveolar ventilation (V_A) and CO_2 clearance. Consequently, CMV is useful in conditions where there is alveolar hypoventilation (e.g. respiratory muscle weakness), when $PaCO_2$ needs to be maintained in a fixed range (e.g. raised intra-cranial pressure) or when the work of breathing must be minimised (e.g. severe cardiorespiratory failure). Because CMV may not match respiratory drive, and spontaneous, supported or assisted breaths are not possible during CMV, sedation and sometimes muscle paralysis may be needed. CMV is usually combined with $PEEP_e$, which can recruit collapsed lungs and reduce intrapulmonary shunt. The components are discussed below.

Tidal Volume

Larger V_T, typically 12–15 mL/kg, or intermittent recruitment manoeuvres (sighs) prevent progressive atelectasis and intrapulmonary shunt during general anaesthesia.[24] However, this may result in excessive lung stretch, leading to ventilator-induced lung injury (VILI). For example in (ARDS), V_T of 6 mL/kg versus 12 mL/kg predicted body weight (i.e. often 4–5 mL/kg vs. 9–10 mL/kg true weight) reduced mortality from 40% to 31%.[25] Consequently, lower V_T should be strongly considered during CMV, and other forms of ventilatory assistance, in patients with ARDS; however, greater levels of PEEP are usually required. Whereas the reduction in V_T is particularly applicable to ARDS where a smaller proportion of the lung is ventilated (see Chapter 37) clinical outcomes are improved with protective lung ventilation in both critically ill patients without ARDS and following general anaesthesia.[26, 27] Intermediate V_T offers more efficient V_A when ventilator support is required for obstructive lung disease, as the anatomical dead space fraction is lower.

Respiratory Rate (*f*)

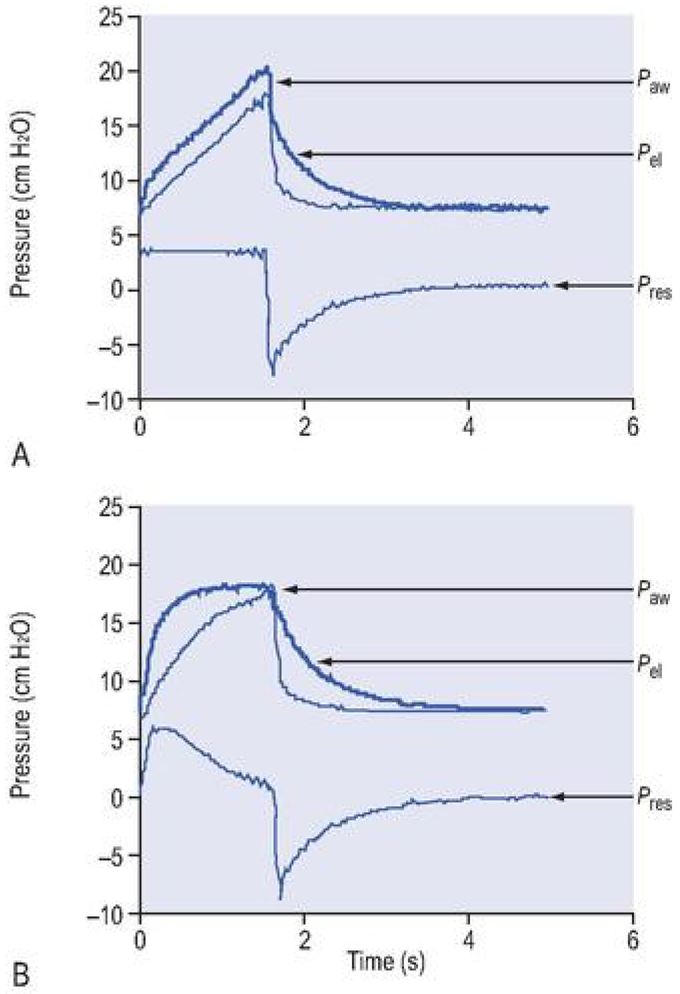
The desired minute ventilation is determined by the product of V_T and f. Common CMV rates are 10–20 breaths per minute in adults. Sufficient expiratory time (T_e) must be allowed to minimise dynamic hyperinflation and PEEP_i. Although high f (up to 35 breaths per minute) was allowed in the ARDS Network protocol, and the low V_T, low mortality group had a mean f of ~30 breaths per minute,[25] laboratory data suggest a possible additive role of high f in VILI.[28]

Inspiratory Flow Pattern

The simplest form of CMV uses a constant inspiratory $\dot{\boldsymbol{V}}$ ($\dot{\boldsymbol{V}}_I$) and, in combination with T_i, a preset volume is delivered. This is also called volume-controlled ventilation (VCV); some ventilators use V_T and T_i to set $\dot{\boldsymbol{V}}_I$. Alternative $\dot{\boldsymbol{V}}_I$ patterns that are commonly available with VCV include a ramped descending flow pattern and a sine pattern. When a time-preset inspiratory pressure is delivered, this is termed pressure-controlled ventilation (PCV).

Although there are no convincing physiological or outcome data differentiating these different modes of CMV,[29] PCV is increasingly used when the peak airway pressure (P_{pk}) is high with VCV. However, the alveolar distending pressure, which is usually inferred from the plateau pressure (P_{plat}), is no different provided that T_i and V_T are the same.[30] During PCV, P_{res} is dissipated during inspiration so P_{pk} and P_{plat} are equal, and during VCV P_{res} accounts for the difference between P_{pk} and P_{plat} (Fig. 42.2). Similarly, different CMV $\dot{\boldsymbol{V}}_I$ patterns will alter P_{pk}

without changing P_{plat} or mean airway pressure (P_{mean}) when T_{i} and V_{T} are constant. In ARDS patients, comparing VCV and PCV there was no difference in haemodynamics, oxygenation, recruited lung volume or distribution of regional ventilation.[31] Although PCV may dissipate viscoelastic strain earlier,[31] high $\dot{\boldsymbol{V}}_{\text{I}}$ may cause or exacerbate VILI,[32] which may explain why some animal models have found PCV, which inherently has a high early $\dot{\boldsymbol{V}}_{\text{I}}$, to be injurious compared with VCV.



The two graphs labelled A and B plot pressure in centimetres of water against time in seconds, which illustrates pressure variations during mechanical ventilation. In both graphs, three pressure curves are shown: airway pressure, oesophageal pressure and transpulmonary pressure. Graph A shows a gradual decline in P a w after a peak, a more negative P e s curve, and a calculated P t p. Graph B shows a similar pattern with slightly higher P a w and less negative P e s compared to A. Time axis ranges from 0 to 6 seconds, with vertical shifts in curves representing inspiratory and expiratory phases. Arrows label each pressure curve, and distinctions between peak, plateau, and baseline phrases are marked.

FIG. 42.2 Actual pressure-time data from a patient with acute respiratory distress syndrome ventilated with volume-controlled ventilation *(panel a)* , and then with pressure-controlled ventilation *(panel b)* ; tidal volume, I:E ratio and respiratory rate are constant. The airway pressure (P_{aw} , *bold line*) has been broken down to its components, P_{el} and P_{res} (see Fig. 42.1). Although there is no inspiratory pause, there is marked similarity between *panel a* and Fig. 42.1 , with the inspiratory difference between P_{aw} and P_{el} due to a constant P_{res} . In *panel b* , the decelerating inspiratory flow pattern seen with pressure-controlled ventilation results in dissipation of P_{res} by end inspiration. Consequently, during pressure-controlled ventilation $P_{aw} \approx P_{plat}$ obtained during volume-controlled ventilation. In other words, for the same ventilator settings, there is no difference in the elastic distending pressure.

Pressure-regulated volume control (PRVC) is a form of CMV where the V_T is preset and achieved at a minimum pressure using a decelerating flow pattern.

Inspiratory Pause

An end-inspiratory pause allows examination of the decay in P_{pk} , and measurement of P_{plat} , and may alter the distribution of ventilation. If T_i and V_T are maintained constant, there is no improvement in oxygenation, and a more rapid $\dot{V}_I$ will be needed. Theoretically, during an end-inspiratory pause, 32% of the total energy loss within the respiratory system will be dissipated, [33] which may significantly reduce the forces driving expiration, potentially exacerbating gas trapping in patients with severe airflow limitation.

Inspiratory Time, Expiratory Time, I:E Ratio

The combination of V_T and inspiratory $\dot{V}$ will determine T_i , which in combination with f sets T_e . A typical T_i is 0.8–1.2 seconds; with a V_T of 500 mL and inspiratory $\dot{V}$ of 0.5 L/s, the T_i is 1.0 second. During spontaneous ventilation, the distribution of ventilation at low $\dot{\boldsymbol{V}}$ is determined by regional E, and at high inspiratory $\dot{\boldsymbol{V}}$ by regional R, leading to greater ventilation of non-dependent lung. In patients with severe airflow limitation, high inspiratory flow rates may be used in order to prolong T_e and minimise dynamic hyperinflation.[34]

The I:E ratio is usually set at or below 1:2 to allow an adequate T_e for passive expiration. During inverse-ratio ventilation (IRV), the I:E ratio is greater than 1:1. The putative benefits of a prolonged T_i include higher expiratory $\dot{\boldsymbol{V}}$ and improved mucus clearance,[35] recruitment of long time-constant alveoli and a short T_e results in gas trapping and PEEP_i. Early reports of clinical benefit did not control for PEEP_i, and, when total PEEP, f and V_T are constant,[30],[31] pressure-controlled inverse-ratio ventilation (PCIRV) tends to reduce $PaCO_2$ but does not improve oxygenation, and may have deleterious haemodynamic effects and exaggerate regional overinflation.[31]

Positive End-Expiratory Pressure

Positive end-expiratory pressure (PEEP) is an elevation in the end-expiratory pressure upon which all forms of mechanical ventilation are to be imposed. When PEEP is maintained throughout the respiratory cycle in a spontaneously breathing subject, the term constant positive airway pressure (CPAP) is used. The primary role of PEEP is to maintain recruitment of collapsed lungs, increase FRC and minimise intrapulmonary shunt. PEEP may also improve oxygenation by redistributing lung water from the alveolus to the interstitium and, although there is no direct effect of PEEP to reduce extravascular lung water, this may occur in patients with left ventricular failure due to a reduction in venous return and left ventricular afterload. Furthermore, inadequate PEEP may contribute to VILI by promoting tidal opening and closing of alveoli. PEEP levels of 5–15 cm H_2O are commonly used, and levels up to 25 cm H_2O may be required in patients with severe ARDS. Although meta-analysis of three large multicentre trials[36] found no benefit of higher PEEP levels in ARDS, mortality was lower in more hypoxaemic patients and there were fewer rescue therapies required, suggesting individual titration may need to be considered. However, in ICU patients without ARDS who were expected not to be extubated within 24 hours, a lower PEEP strategy was non-inferior to a higher PEEP strategy with regard to the number of ventilator-free days at day 28.[37]

PEEP titration in ARDS is complex (see Chapter 37), and should aim to improve oxygenation and minimise VILI. Since PEEP reduces venous return, cardiac output and O_2 delivery may fall despite an improvement in Pa_{O_2} ; indeed, this concept has been used to optimise PEEP in ARF.[38] However, in addition to recruitment, increasing PEEP may lead to overinflation of non-dependent alveoli that are already aerated at the end expiration.[39,40] Patients with focal ARDS are a particular risk group as recruitment is limited; VILI can be minimised when PEEP is reduced below standard levels.[41] In general, overinflation and VILI are less likely if alveolar distending pressure is kept less than 30–35 cm H_2O, or the change in driving pressure is less than 2 cm H_2O when V_T is constant.[42]

PEEP$_e$ is applied by placing a resistance in the expiratory circuit (Fig. 42.3), with most ventilators using a solenoid valve. Independent of the technique, a threshold resistor is preferred since it offers minimal resistance to flow once its opening P is reached. This will minimise expiratory work, and avoid barotrauma during coughing or straining.

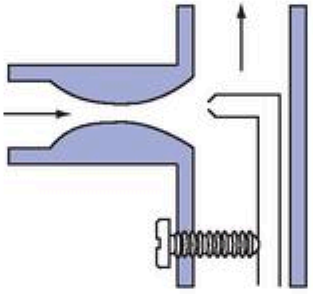
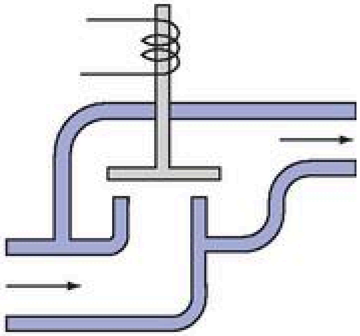
Weight



Venturi



Pressure-activated solenoid

The six schematic diagrams are arranged in two columns. The top left represents a narrowed pipe with a screw indicating flow restriction by constriction. The top right shows a coiled spring compression under fluid flow. The middle left diagram illustrates a pipe submerged in a bubbling water column. The middle right shows a funnel-like structure pressed down by a weight in a branching pipe. The bottom left diagram demonstrates a Venturi mechanism where narrowing increases flow velocity. The bottom right shows a pressure-activated solenoid controlling fluid direction within a pipe. All diagrams include arrows which show the flow direction and components for mechanical regulation.

FIG. 42.3 Positive end-expiratory pressure values.

PEEP$_{\mathrm{i}}$ is an elevation in the static recoil pressure of the respiratory system above PEEP$_{\mathrm{e}}$ at end expiration. PEEP$_{\mathrm{i}}$ arises due to an inadequate T_{e}, usually in the setting of severe airflow obstruction. However, it may be a desired end-point during IRV. The sum of PEEP$_{\mathrm{e}}$ and PEEP$_{\mathrm{i}}$ is the total PEEP (PEEP$_{\mathrm{tot}}$). The distribution of PEEP$_{\mathrm{i}}$ is likely to be less uniform than an equivalent PEEP$_{\mathrm{e}}$; this may not have the same physiological effects. When patients with severe airflow obstruction are triggering ventilation, PEEP$_{\mathrm{e}}$ less than PEEP$_{\mathrm{i}}$ may be applied to reduce elastic work (see later in the chapter, Patient–Ventilator Interaction).

Fractional Inspired Oxygen Concentration (Fi_{O_2})

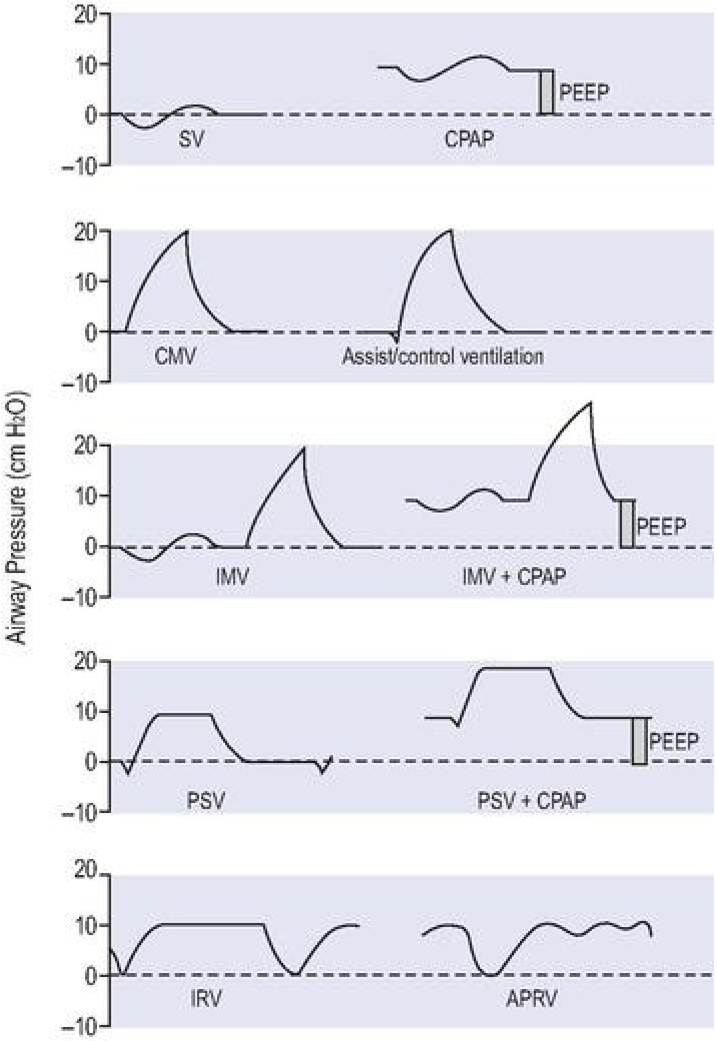
Adequate arterial oxygen saturation is achieved through a combination of minute ventilation, PEEP and Fi_{O_2} adjustment. Even patients with normal respiratory systems usually need an $Fi_{O_2} > 0.21$ due to ventilation-perfusion mismatch secondary to positive-pressure ventilation. In patients with ARF, it is common to start with an $Fi_{O_2} \leq 0.6$ of 1 and titrate down as PEEP and minute ventilation are adjusted. Because high $Fi_{O_2}s$ are damaging to the lung, and nitrogen washout may exacerbate atelectasis, it is reasonable to aim at an $Fi_{O_2} \leq 0.6$. The target PaO_2 or SpO_2 remains controversial; as both hypoxaemia and hyperoxia increase the risk of adverse clinical outcomes,[43-47] normoxia should be targeted until further evidence is available.

Sigh

Many ventilators can intermittently deliver a breath at least twice V_T. Sighs may reduce atelectasis, in part, through release of pulmonary surfactant,[48] resulting in recruitment and improved oxygenation in ARDS and a less frequent use of rescue therapy.[49,50] However, if sighs or recruitment manoeuvres are used, care must be taken to avoid recurrent excessive lung stretch as it can be associated with negative effects such as hemodynamic impairment.[50]

Assist-Control Ventilation

During assist-control ventilation (ACV), in addition to the set f, patient effort can trigger a standard CMV breath (Fig. 42.4). This allows greater patient comfort, and V_T is controlled at a safe level; however, there may be little reduction in respiratory work compared to an unassisted breath at low $\dot{\boldsymbol{V}}_I$ because the respiratory muscles continue to contract through much of the breath.[51] The equivalent PCV breath is termed pressure assist-control ventilation (PACV). Differences between triggering modes will be discussed later in the chapter (Patient–Ventilator Interaction).



The series of pressure-time waveforms illustrates eight airway pressure versus time graphs, including S V, C P A P, C M V, I M V, P S V, I R V, and A P R V, with P E E P indicated where applied, each representing a distinct mechanical ventilation mode. In Spontaneous Ventilation, low baseline pressure oscillations occur around zero. Continuous Positive Airway Pressure maintains pressure above zero. Controlled Mechanical Ventilation shows regular, large, uniform pressure peaks, while Assist or Control Ventilation features similar patterns with variation. Intermittent Mandatory Ventilation combines regular machine breaths with spontaneous ones, and I M V plus C P A P adds a positive baseline pressure. Pressure Support Ventilation displays irregular pressure spikes from patient-initiated assisted breaths, and P S V plus C P A P shows the same with an elevated baseline. Inverse Ratio Ventilation extends the inspiratory phase relative to expiration, and Airway Pressure Release Ventilation maintains a high baseline with intermittent drops, signifying periodic pressure releases. Positive end-expiratory pressure is evident as elevated baselines in C P A P, I M V plus C P A P, P S V plus C P A P, and A P R V.

FIG. 42.4 Schematic representation of airway pressure versus time for a variety of forms of ventilatory assistance. *APRV* , Airway pressure release ventilation; *CMV* , controlled mechanical ventilation; *CPAP* , continuous positive airway pressure; *IMV* , intermittent mandatory ventilation; *IRV* , inverse-ratio ventilation; *PEEP* , positive end-expiratory pressure; *PSV* , pressure support ventilation; *SV* , spontaneous ventilation.

Intermittent Mandatory Ventilation, Synchronised Intermittent Mandatory Ventilation

Intermittent mandatory ventilation (IMV) was introduced over 20 years ago to aid weaning from CMV by allowing the patient to take ‘unimpeded’ breaths while still receiving a background of controlled breaths. Proposed advantages include a reduction in sedation, lower mean intrathoracic pressure with less barotrauma and adverse haemodynamic consequences, improved intrapulmonary gas distribution, continued use of respiratory muscles and faster weaning. During synchronised intermittent mandatory ventilation (SIMV) T_i is partitioned into patient-initiated and true spontaneous breaths to avoid breath stacking. However, during spontaneous breaths the work of breathing imposed by the endotracheal tube, circuit and ventilator must be overcome.[52] In weaning studies comparing SIMV with T-piece trials and pressure support ventilation (PSV), SIMV is the slowest.[53] Many clinicians add PSV during gradual reduction in respiratory rate with SIMV to overcome the added respiratory work imposed by the circuit and endotracheal tube; however, this approach has not been formally compared with other weaning techniques, and upper-airway oedema following extubation increases extubated W_{res} similar to that imposed by the endotracheal tube prior to extubation.[54]

Pressure Support Ventilation

During PSV, each patient-triggered breath is supported by gas flow to achieve a preset pressure, usually designated to be above the $PEEP_e$. This can be explained by referring to the equation of motion where:

$$P_{mus} + P_{ao} = E_{rs} \cdot V + R_{rs} \cdot \dot{V} + P_o \tag{42.6}$$

During PSV, P_{ao} is the targeted variable by the ventilator, which leads to a significant and important reduction in P_{mus} and work of breathing.[55] The detection of neural expiration varies between ventilators, but commonly relies upon a fall in the inspiratory $\dot{V}$ to either 25% of the initial flow rate or to less than 5 L/min; some ventilators allow titration of the percentage reduction in initial flow to allow improved patient–ventilator synchrony. PSV may also be titrated to offset the work imposed by the circuit and endotracheal tube. The absolute level required to offset this will vary with endotracheal tube size and inspiratory $\dot{V}$,[56] but is commonly 5–10 cm H_2O.[57] PSV can be used during weaning, or as a form of variable ventilatory support with pressures of 12–15 cm H_2O commonly used. Disadvantages include variable V_T, and hence minute ventilation, the potential to deliver an excessive V_{T} (common in patients recovering from ARDS) and patient–ventilator asynchrony, which is common with high levels of PSV (see later).

Volume-assured pressure support (VAPS) is a mode of adaptive PSV where breath-to-breath logic achieves a preset V_{T} .

Proportional Assist Ventilation

Proportional assist ventilation (PAV) is a form of partial-ventilatory support where inspiratory P is applied in proportion to patient effort. Because this allows the breathing pattern and minute ventilation to be matched to patient effort, it is only suitable if respiratory drive is normal or elevated. In concept, this should optimise the patient–ventilator interaction; however, the prescription of PAV requires a greater level of physiological understanding than similar forms of partial-ventilatory support such as PSV, since there is no target P , V or $\dot{V}$. PAV is usually prescribed using volume assist (VA) and flow assist (FA), with V and $\dot{V}$ measured continuously. VA generates greater P as V increases, leading to elastic unloading, and FA generates greater P as $\dot{V}$ increases, leading to resistive unloading. Not surprisingly, the units of VA are cm H_2O/L (i.e. an elastance term) and those for FA are cm H_2O/L/s (i.e. a resistance term). This can be illustrated by referring to Eq. (42.6) :

$$\mathrm{P}_{\mathrm{mus}} + P_{\mathrm{ao}} = E_{\mathrm{rs}} \cdot V + R_{\mathrm{rs}} \cdot \dot{V} + P_{\mathrm{o}}$$

where P_{ao} is determined by PAV, where PAV = VA + FA, so:

$$P_{\mathrm{mus}} + \mathrm{VA} \cdot V + \mathrm{FA} \cdot \dot{V} = E_{\mathrm{rs}} \cdot V + R_{\mathrm{rs}} \cdot \dot{V} + P_{\mathrm{o}} \quad \textbf{(42.7)}$$

If E_{rs} and R_{rs} are known, PAV can, at least in principle, be targeted to reduce a specified proportion of either, or both, elastic and resistive respiratory work. For example, when VA and FA are adjusted to counterbalance E_{rs} and R_{rs} so as to achieve normal values, minute ventilation increases, and respiratory drive and work decrease; if PEEP$_i$ is present, work can be further reduced by applying PEEP$_e$.[58] Respiratory mechanics are relatively hard to estimate in spontaneously breathing patients, and although they are now offered on some ventilators, their accuracy has been questioned,[59] which may reduce the validity of adjusting PAV according to estimated load (PAV+). Consequently, PAV is often titrated to patient comfort. Despite a growing body of data demonstrating reduced work of breathing, and improved patient–ventilator synchrony with PAV, it is a more difficult technique to use, and definitive studies showing a clinically important outcome difference are awaited.

Neurally Adjusted Ventilatory Assistance

During neurally adjusted ventilatory assistance (NAVA), a modified nasogastric tube is used to record diaphragmatic electrical activity, which is used to control the assisting level of inspiratory pressure. This short-circuits trigger and feedback functions with improved patient–ventilator interaction, less asynchrony and less overassistance compared with PSV[60] in small physiological trials. However, in a multicentre trial[61] of 128 patients, although NAVA was well tolerated and reduced asynchrony overall, autocycling and double triggering were more common, there was no clinically significant benefit compared to PSV, and a pneumothorax resulted from misplacement of the NAVA catheter. NAVA may also improve oxygenation, perhaps by allowing more variable V_T consistent with the concept of biological variability. Although NAVA is available on some commercial ventilators, its use is limited, and there are no data showing a clinically important benefit.

Bilevel Ventilation

Also described as biphasic positive airway pressure (BIPAP), this is a ventilatory mode where two levels of airway pressure are provided. Cycling between these two levels of airway pressure may be time cycled or triggered by ventilatory effort, in which case inspiratory positive airway pressure (IPAP) and expiratory positive airway pressure (EPAP) are set; however, this is no different to equivalent support with PSV and PEEP. Patient-triggered bilevel ventilation is most commonly used during NIV.

Airway Pressure Release Ventilation

During airway pressure release ventilation (APRV), spontaneous breathing is possible in addition to time-triggered and time-cycled biphasic pressure levels (high and low CPAP). Usually, the time cycling provides a prolonged T_i aimed at recruiting slow time-constant air spaces. Minute ventilation and CO_2 excretion are augmented by brief (1–1.5 seconds) periodic cycling to the lower level of CPAP. A 'personalised' form of APRV has been described where the expiratory time is set using the end-expiratory flow as a fraction of the peak expiratory flow, typically a ratio of 75% with a Te of 0.3–0.6 seconds.[62] As the augmented V_T is dependent upon elastance of the respiratory system, it will be smaller in patients with 'stiff' respiratory systems. APRV without spontaneous breathing has a similar pressure profile to PCIRV.

APRV offers a number of benefits and is usually applied during IV. The prolonged T_i is usually associated with improved oxygenation at a similar or lower P_{aw} to conventional ventilation. Spontaneous respiratory efforts may: (1) improve matching of ventilation and perfusion due to increased dependent aeration, (2) increase venous return and hence cardiac output or pulmonary blood flow in infants following cardiac surgery[63] and (3) promote reduced sedation and use of neuromuscular blockers.[64], [65] However, while there are encouraging case series and physiological studies,[63], [66] randomised clinical trials have not shown improved outcomes,[67], [68] unsupported spontaneous breaths may increase left ventricular afterload and promote ventilator-patient asynchrony and, as slow time-constant air spaces are also slow to empty, APRV is contraindicated in COPD and asthma. This mode has physiological rationale for its effects on oxygenation and potential to limit VILI, but no specific recommendations can be made given the lack of good outcome data.

High-Frequency Ventilation

High-frequency ventilation (HFV) encompasses techniques where small V_T (1–3 mL/kg) are delivered at high f (100–600/min). This offers reduced tidal lung stretch and reduced VILI. Hazards include inadequate humidification and gas trapping in patients with severe airflow limitation. High-frequency jet ventilation (HFJV) utilises dry gas from a high-pressure source delivered into an intratracheal catheter or specifically manufactured endotracheal tube. Although HFJV has been used with improvement in gas exchange in adults with ARDS,[69] high-frequency oscillation (HFO) has received more interest, including neonatal, paediatric and adult use.

HFO uses oscillatory flow within the airway to provide active inspiration and expiration at rates of 3–10 Hz. There are a number of putative mechanisms of gas exchange in addition to the more usual bulk flow seen during CMV and SV.[70] Ventilation and V_T are determined by the driving pressure, which controls the reciprocating flow, and by $1/f$. Oxygenation is determined by the mean P_{aw} sometimes in combination with recruitment manoeuvres which influence the volume of recruited lung. Typically, the mean P_{aw} is set at 5 cm H_2O above the CMV value.[71] Although the mean P_{aw} during HFO is theoretically dissipated with lower alveolar pressures, and this appears to be the case in homogeneous lung injury, damaged regions of the lung with low compliance, and hence short time constants, may be exposed to alveolar pressures approaching mean P_{aw},[72] resulting in regional VILI.

Although oxygenation is improved in both infants and patients with ARDS, definitive outcome data are lacking. HFO appears to be equivalent to CMV in preterm infants with similar mortality and chronic lung disease.[73] In ARDS, two large randomised trials have reported either no improvement (OSCAR trial),[74] or an increase (OSCILLATE trial)[75] in mortality (47% vs. 35% at hospital discharge). Contributing factors include greater vasopressor use, and greater use of sedation and neuromuscular blockade, with a tendency to greater positive balance, consistent with higher mean airway pressure leading to reduced venous return and greater right ventricular strain.[76] These data refute a meta-analysis that suggested reduced mortality with HFO[77]; however, the largest trial included in this analysis administered a V_T of around 10.6 mL/kg predicted body weight in the control CMV group as compared with protective ventilation in the OSCAR and OSCILLATE studies. Unless new clinical trial data become available, HFO cannot be recommended for routine care in adult ARDS.

Respiratory Drive

Respiratory drive is the intensity of the respiratory centre's output, and it determines the effort exerted during each breath. There are adverse effects associated with both strong and weak respiratory efforts during mechanical ventilation in the critically ill patient.[78] Its estimation and optimisation have become common in the modern practice in mechanically ventilated patients.

Critical illness affects the patient's respiratory drive through multiple mechanisms. The presence of high respiratory drive may induce injurious strenuous breathing and dyspnoea, whereas low respiratory drive may lead to weak inspiratory efforts and apnoeas. Considering the determinants of a patient's respiratory drive at the bedside may facilitate a better understanding and management of the patient and the ventilator, potentially avoiding some of the complications associated with high and low respiratory drive. Airway occlusion pressure ($P_{0.1}$) is the drop in P_{aw} during the first 100 milliseconds of an inspiratory effort against an occluded airway. The rationale to use it as an indicator of drive is that $P_{0.1}$ increases proportionally with a rise in $PaCO_2$[79,80] and during the short occlusion abnormal respiratory mechanics do not affect the measurement. In healthy adults breathing at rest, $P_{0.1}$ ranges between 0.5 and 1.5 cm H_2O. In mechanically ventilated patients, values above 3.5 cm H_2O have been associated with elevated respiratory muscle effort and indicate high drive.[81] $P_{0.1}$ is easily obtained in the ICU because it is an automated measurement available on the majority of modern ventilators, [82] but some issues such as severe muscle weakness, presence of intrinsic positive end-expiratory pressure (PEEPi) and breath-to-breath variability need to be considered. Notwithstanding these potential pitfalls, $P_{0.1}$ may provide indications of changes in drive. [78] Other ways of measuring respiratory drive are the use of electrical activity of the diaphragm (EAdi) – recorded using surface electrodes or via an oesophagal catheter or transdiaphragmatic and inspiratory pressure; however, these are not commonly used.

Respiratory Effort

The evaluation of patient effort is pivotal, especially during supported ventilation and this should not be confused with respiratory drive. [78] However, a non-invasive, continuous, quantitative method to assess patient inspiratory effort is still lacking. Flow index is a novel quantitative, continuous, non-invasive evaluation of the concavity of the inspiratory flow profile and has been associated with patient inspiratory effort during PSV, [83] however, additional research is needed to evaluate the potential impact of assessing the Flow Index on patient–ventilator interaction and weaning from mechanical ventilation.

Another way to measure this respiratory effort is by examining the swing in airway pressure generated by respiratory muscle effort during assisted ventilation when the airway is briefly occluded (ΔP_{occ}). [84] Measuring ΔP_{occ} enables accurate non-invasive detection of elevated respiratory muscle pressure and dynamic transpulmonary driving pressure. However, more research is required as (1) excessive respiratory effort and transpulmonary driving pressure can be frequent in spontaneously breathing ventilated patients, and (2) the impact on clinical outcomes is unclear.

Mechanical Power (MP)

No single parameter provides a clear indication for the onset of lung injury attributable exclusively to the ventilator. One concept that has emerged is the amount of energy transferred from the ventilator to the respiratory system. During mechanical ventilation, energy changes from electrical to potential, kinetic and heat energy as the pressure is generated to move the volume of air known as tidal volume into the lungs. This transfer of energy per unit time is called mechanical power (MP), [85], [86] and this may cause structural changes at the cellular and tissue level in the lung parenchyma contributing to lung injury. [87], [88]

MP shows promise as an indicator of VILI and also highlights the contribution of inspiratory flow rate and respiratory rate to it. [86] However, in the absence of randomised controlled trials, more research is needed to define how this parameter may be used to further identify lung-protective strategies beyond the use of low tidal volume based on ideal body weight or safe driving pressure. [85]

Indications and objectives of mechanical ventilation [89]

Institution of mechanical ventilation is a clinical decision; it can only be supported by parameters such as blood gases or measures of respiratory muscle function. Even then, the decision to choose IV over NIV will be influenced by numerous factors including the indication and its likely course. Often there will be an indication for intubation (Box 42.1) and mechanical ventilation; however, if intubation is required to overcome upper-airway obstruction, no ventilatory assistance may be needed despite the increase in respiratory work imposed by the endotracheal or tracheostomy tube. [52] Once the decision has been made to proceed to ventilatory support, the choice of mode should be based on a physiological approach, local expertise and simplicity.

Box 42.1

Indications and objectives of intubated mechanical ventilation

Endotracheal intubation or tracheostomy

- For airway protection (e.g. coma)
- For suction of secretions
- To assist sedation and neuromuscular paralysis (e.g. to ↓ $\dot{V}_{O_2}$ ↓ *respiratory distress*)
- To overcome upper-airway obstruction

Mechanical ventilation

- To manipulate alveolar ventilation (V_A) and $PaCO_2$ (e.g. reverse respiratory acidosis, ↓ cerebral blood flow and intra-cranial pressure)
- To ↑ Sa_{O_2} and Pa_{O_2} (by ↑ FRC, ↑end-inspiratory lung volume, ↑ V_A , ↑ Fi_{CO_2})
- To ↓ work on breathing (e.g. to overcome respiratory muscle fatigue)
- To ↑ FRC (e.g. ↑ Pa_{O_2} , ↓ ventilator-induced injury)
- To control lung stretch during spontaneous breathing, non-invasive ventilation or partially assisted ventilation
- To stabilise the chest wall in severe chest injury

Patients who are likely to need ventilatory assistance (e.g. acute severe asthma) should be considered for early ICU admission since this will allow faster responses and avoid cardiorespiratory arrest. Specific issues and methods of ventilatory assistance are dealt with in the chapters on ARDS, asthma, COPD and NIV. In patients with traumatic brain injury, IV is commonly required to protect the airway and to assist control of ICP; similarly, patients with severe pancreatitis or serious abdominal infection may need prolonged IV to maintain an adequate FRC, reduce work of breathing, protect their airway and allow suctioning of secretions.

Minimisation of Lung Injury

Protective ventilation aims to minimise excessive regional lung stretch and cyclic recruitment and collapse, and reduce VILI. Typical protective ventilation combines V_T of 6 mL/kg pbw [25] combined with moderate PEEP [36] and plateau pressures less than 30 cm H_2O (see Chapter 37 , ARDS for further discussion). Although the focus has been on protective ventilation during CMV, these processes can occur during spontaneous breathing without ventilator assistance, and during both NIV and partial ventilator support. High respiratory drive due to lung injury or metabolic acidosis may result in relatively large V_T ; despite reducing ventilator support, regional differences in aeration can lead to pendelluft (movement of gas between two regions of the lung, usually between regions of differing compliance or airway resistance) and lung injury compared to a controlled breath at the same V_T and transpulmonary pressure, and falls in alveolar pressure may result in greater transmural vascular pressure and pulmonary oedema. [90] The corollaries of this include great care when providing partial ventilator support, and VILI prophylaxis as a possible indication for mechanical ventilation (see Box 42.1).

Initiation of Intubated Mechanical Ventilation

A manual resuscitation circuit, mechanical ventilator and equipment for safe endotracheal intubation should be available. Initial ventilator settings are commonly set to achieve adequate oxygenation and V_A ; however, this will depend upon the patient's condition. Common settings are V_T 6–8 mL/kg, f 10–20 breaths/min, PEEP 5 cm H_2O and Fi_{O_2} 1.0, and these will need to be adjusted according to the specific pathophysiology and response.

Manual Resuscitation Circuits

Manual resuscitation circuits are primarily used to provide emergency ventilation when spontaneous effort is absent or inadequate. They may be used with a face or laryngeal mask, or an endotracheal tube. Occasionally they are used to provide a high inspired O_2 concentration during spontaneous breathing; however, this may impose significant additional respiratory work. [91] In the ICU they are commonly used for preoxygenation and manual lung inflation.

Their basic design includes a fresh gas flow of O_2, a reservoir bag and valves to allow spontaneous or positive-pressure breathing. Most manual resuscitation circuits use a self-inflating reservoir bag since this allows the circuit to be used by unskilled personnel and does not require a fresh gas flow. However, circuits using reservoir bags that are not self-inflating are still used in some institutions since they allow a better manual assessment of the respiratory mechanics, the ‘educated hand’, and it is clear when there is an inadequate seal with a mask. Oxygen-powered manually triggered devices have been used for many years; however, their use has declined markedly since high $\dot{V}$ and P may lead to barotrauma or gastric inflation.

Self-inflating reservoir bags use a series of one-way valves to allow fresh gas flow oxygen and entrained air to fill the bag. Inspired oxygen fractions as high as 0.8 may be achieved with neonatal or paediatric bags when an additional reservoir bag is used to allow fresh gas flow filling during expiration after the bag has refilled.[92] However, lower $Fi_{O_2}s$ (~0.6) will be obtained with both conventional O_2 flow rates of 8–15 L/min, and usual V_T and f, with an adult bag. Generally, the valves are simple flap or duckbill in nature, and both positive-pressure and spontaneous ventilation are possible. The reservoir bag volume in adults is typically 1600 mL, and V_T can be judged from chest wall movement. It is essential these devices use standard 15/22 mm connectors to allow rapid connection to standard endotracheal tubes and ventilator circuits.

Patient–Ventilator Interaction

During partial-ventilatory support or spontaneous breathing, the ventilator should match neural drive; however, suboptimal patient–ventilator interaction, also termed asynchrony, is common, frequently not diagnosed and is associated with prolonged mechanical ventilation, increased length of stay both in hospital and in the ICU, and with increased mortality when more than 30% of breaths are asynchronous.[93] Clinical signs of asynchrony include agitation, diaphoresis, tachycardia, hypertension and failure of weaning or NIV. Once this pattern is identified, it is crucial that airway complications (partial obstruction and displacement) or a major change in the clinical state (e.g. pneumothorax and acute pulmonary oedema) are excluded before considering problems with patient–ventilator interaction.

Although both PAV and NAVA reduce asynchrony, they are complex and less commonly used. Recognition and management of asynchrony are assisted by a physiological approach to the respiratory cycle: (1) triggering of inspiration, (2) inspiration and (3) cessation of inspiration. Difficulties at each of these phases will lead to changes in respiratory drive and effort that may be expressed throughout the respiratory cycle. Careful bedside observation of the patient–ventilator interaction is essential, as isolated observation of P, V and $\dot{\boldsymbol{V}}$ waveforms displayed by the ventilator leads to under-recognition of asynchrony. In one series [94] ineffective triggering accounted for most of the asynchronous episodes with autocycling the next most common cause. Prevalence of asynchrony increased with PSV ≥12 cm H_2O, large V_T and low respiratory rates in part reflecting dynamic hyperinflation and PEEP$_i$.

Triggering of Inspiration

1. PEEP$_i$ is an important hindrance to the triggering of inspiration in patients with severe airflow limitation, since their inspiratory muscles must first reduce P_{ao} below ambient pressure. [95] Consequently, P_{mus} must exceed PEEP$_i$ prior to triggering an assisted breath, usually by either reducing airway pressure (pressure trigger) or reducing circuit flow (flow trigger). This inspiratory threshold load may be up to 40% of the total inspiratory work in ARF when dynamic hyperinflation is present, and commonly results in ineffective triggering. Triggering can be markedly improved and respiratory work reduced by low levels of PEEP$_e$, [95], [96] commonly 80%–90% of dynamic PEEP$_i$ [97] if this is measured.
2. Patient effort may be sensed, and the ventilator cycled (triggered) to inspiratory assistance, by changes in any of P_{ao}, flow, volume, shape-signal and detection of neural drive (NAVA). During pressure triggering a fall in P_{ao} is usually sensed at the expiratory block of

the ventilator. Sensing at the Y-piece may not be superior since there can be a similar delay in sensing, as the transducer is usually sited in the ventilator (the usual position) and this demands a similar or greater length of gas tubing. Flow triggering senses a fall in continuous circuit flow, and was introduced as a method of reducing inspiratory work. However, there has been a marked improvement of both pressure and flow triggering in modern ventilators with the trigger time delay falling from ~400 ms to <60 ms in most modern ventilators,[98] and a similar improvement in the maximum fall in airway pressure[99]; consequently, ventilator triggering contributes about 5% of respiratory effort. Attempts to improve the trigger function by oversetting the pressure sensitivity (< -0.5 cm H_2O) may lead to autocycling, which may also occur with overset flow triggering. This is due to the P and $\dot{V}$ effects of cardiac oscillations, hiccups, circuit rainout or mask leak with NIV and has been reported as a cause of apparent respiratory effort in brain-dead patients.[100] Flow triggering reduces the risk of autocycling at a given trigger sensitivity, and reduces respiratory effort a small amount compared with pressure triggering; however, it does not alter the frequency of ineffective efforts, or patient effort following triggering.[98] A combination of shape-signal and volume triggering is used on some ventilators; the increased sensitivity of shape-signal triggering reduces effort but increases autocycling.[98]

Inspiration

Once inspiration is triggered or sensed by the ventilator, $\dot{V}$ is determined by P, T_i or $\dot{V}$. For example during PSV ventilation a target P is held until expiration is sensed, and during ACV $\dot{V}$ is held for a set T_i. During ACV there may be continued inspiratory effort, and since inspiratory $\dot{V}$ is fixed, this will be reflected by a scalloping of the $P_{ao} - T$ graph if $\dot{V}$ is inadequate. Again this may be illustrated using the equation of motion:

$$P_{\mathrm{mus}} + P_{\mathrm{ao}} = E_{\mathrm{rs}} \cdot V + R_{\mathrm{rs}} \cdot \dot{V} + P_{\mathrm{o}} \qquad \textbf{(42.8)}$$

P_{mus} will reflect the difference between P_{ao} due to E, R and P_o and the observed P_{ao}. In contrast, during P-cycled ventilation (PACV) greater patient effort is rewarded and inspiratory work is lower than during equivalent ACV.[101]

Modern ventilators allow adjustment of inspiratory $\dot{V}$ and $\dot{V}$ pattern, and the rate of rise of P_{ao}. Low inspiratory $\dot{V}$ rates during ACV result in significant inspiratory work, but this may be markedly reduced by increasing inspiratory $\dot{V}$ to 65 L/min.[102] However, these issues are quite complex, and f increases (probably due to a lower respiratory tract reflex) as $\dot{V}_I$ increases,[103] reducing T_e, which may contribute to dynamic hyperinflation in patients with severe airflow obstruction. During PSV and PACV, many ventilators allow adjustment of the rate of rise of P to its target. Although an excessively steep P ramp leads to earlier attainment of the P target and greater early $\dot{V}$ rates, this is associated with increased dyspnoea and effort, as is too flat a P ramp.[98]

Cessation of Inspiration/Cycling

During PSV, an increase in airway resistance will result in a longer expiratory time constant and a delayed fall in $\dot{V}_I$. Since this is the usual trigger for cycling to expiration, the ventilator may continue to provide $\dot{V}_I$ while the patient desires to exhale. This commonly leads to recruitment of expiratory muscles, detected both clinically and as a transient rise in the end-inspiratory P_aO_2.[104] Most modern ventilators allow control of the fall in $\dot{V}_I$ that is sensed as end inspiration; the default is usually a reduction of $\dot{V}_I$ to 25%–30% of the peak $\dot{V}_I$ rate. When airway resistance is high, a higher cycling threshold (e.g. 45%) can reduce T_i, V_T and PEEP$_i$ with reduced trigger effort. However, this may result in premature termination of inspiration in ARDS where the time constant is short. High levels of PSV (≥20 cm H_2O), weak respiratory muscles and mask leak with NIV are other common causes of asynchrony at the termination of inspiration. In this last group, PACV, which is time cycled, allows improved patient–ventilator synchrony at end inspiration compared with PSV. [105]

High V_T, commonly associated with high levels of PSV, often precedes wasted efforts due to shortened T_e and $PEEP_i$. As asynchrony is reduced with less PSV, the optimum level of PSV will occur when there is minimal increase in f and P_{mus}. This typically occurs at a PSV of 13 cm H_2O with V_T 6 mL/kg and T_i 0.8 seconds. [106]

Withdrawal (weaning) from mechanical ventilation

Once the underlying process necessitating mechanical ventilation has started to resolve, withdrawal of ventilatory support should be considered; increased duration of ventilation leads to a progressive rise in complications such as ventilator-associated pneumonia. However, other important parameters that must be considered include the neuromuscular state of the patient (ability to initiate a spontaneous breath), adequacy of oxygenation (typically low requirements for PEEP [5–8 cm H_2O] and Fi_{O_2} [<0.4–0.5]) and cardiovascular stability. [107] Once a patient is considered suitable to wean, a secondary question is whether an artificial airway is still required for airway protection or suction of secretions. Many patients can rapidly make the transition from mechanical ventilation to extubation, but ~20% of patients fail weaning despite meeting clinical criteria. [53] Advanced age, prolonged mechanical ventilation and chronic obstructive pulmonary disease all increase the likelihood that weaning will be difficult. [53]

Weaning failure is usually associated with an increase in respiratory drive, and respiratory rate and a fall in V_T, which contributes to hypercapnea [108]; about 10% of patients fail due to central respiratory depression. Various indices such as maximal inspiratory pressure (MIP), minute ventilation (V_E), f, V_T, f/V_T ratio and the dynamic compliance, respiratory rate, oxygenation, maximum inspiratory pressure (CROP) index have been investigated as predictors of weaning failure (Table 42.1). They are rarely used alone and careful clinical assessment is often adequate, yielding a re-intubation rate as low as 3%, [109] and none of these indices assess airway function following extubation. Although the typical threshold value for the rapid shallow breathing index (f/V_T ratio) is greater than 105, a large multicentre study reported progressive increase in risk as this increased with a threshold of 57; in addition, a positive fluid balance immediately prior to extubation was a significant risk factor for re-intubation. [110] Consequently, weaning indices should not necessarily delay extubation or a weaning trial. However, they may quantitate important issues in the general clinical assessment, and may be directly relevant for a given patient. For example frequent small V_T, an inadequate vital capacity (less than 8–12 mL/kg), large minute ventilation (≥15 L/min), depressed respiratory drive, and reduced respiratory muscle strength (MIP ≤ -15 cm H_2O) or drive should be strongly factored into deciding whether a patient is ready to safely undergo a trial of weaning.

Table 42.1

[a] Although threshold values are often used, the data are not dichotomous. For example as the f/V_T ratio increases, so does the rate of re-intubation. [108]

[b] CROP index = $(C_{\text{dyn}} \times \text{MIP} \times [Pa_{O_2}/PA_{O_2}]/f)$. See reference 94 for further details.

CROP, Compliance, respiratory rate, oxygenation, maximal inspiratory pressure; *MIP*, maximal inspiratory pressure.

Direct comparisons between T-piece trials, PSV and SIMV as weaning techniques have been performed in patients previously failing a 2-hour trial of spontaneous breathing. In the study by Brochard and colleagues, [111] PSV led to fewer failures and a shorter weaning period. In contrast, Esteban and coworkers [112] found that a once-daily trial of spontaneous breathing resulted in the shortest duration of mechanical ventilation; however, a relatively high proportion of patients required re-intubation (22.6%). Viewed together, these studies suggest that weaning was slower with SIMV, [53] although SIMV with PSV was not studied, and that either PSV or a T-piece trial are the preferred methods for weaning. Since low levels of PSV can help compensate for the additional work of breathing attributable to the endotracheal tube and circuit, some clinicians use low levels of PSV (5–7 cm H_2O) during weaning or during a spontaneous breathing trial. However, the work of breathing following extubation is usually higher than expected, probably due to upper-airway oedema and dysfunction so that work is similar to that during a T-piece trial.[53]

Re-intubation is relatively common, with reported rates of 15%, and is associated with a 7–11-fold increased risk of hospital death.[53] Although this may reflect extubation of sicker patients, there does appear to be a specific effect of extubation failure on outcome, perhaps due to the risks of re-intubation itself along with its haemodynamic consequences, and an increased risk of infection. Thille and co-workers[113] reported that 27% of patients developed pneumonia and that 50% of patients died following re-intubation. They identified age greater than 65 years and underlying cardiorespiratory disease as risk factors for extubation failure. Unplanned extubations were associated with higher endotracheal tube position on chest radiograph. Hence, an important goal during mechanical ventilation will be to proceed to early and expeditious extubation with a low re-intubation rate.

Weaning by Protocol Versus Usual Care

There have been RCTs comparing the use of protocols versus usual care in weaning management; and protocolised weaning was found to have been without benefit.[114-116] While some of the other studies have problems of internal validity.[117, 118] In summary, there is not enough research support for protocolised weaning, with the remainder providing no evidence of benefit.

Monitoring with Mechanical Ventilation

Monitoring includes a high nurse:patient ratio (usually 1:1), ventilator alarms, and pulse oximetry. Capnography is required to confirm endotracheal tube placement, both at the time of intubation and during ventilatory support, and may be used to monitor the adequacy of V_A; however, expired CO_2 is strongly influenced by factors that alter alveolar dead space such as cardiac output. Intermittent blood gases, PEEP_i, airway pressures in volume-preset modes and V_T in pressure-preset modes should be recorded. Individual patients may benefit from more extensive monitoring of their respiratory mechanics or tissue oxygenation.

The patient's airway (i.e. patency and presence of leaks and nature and amount of secretions), breathing (i.e. rate, volume and oxygenation), and circulation (i.e. pulse, blood pressure and urine output) must be monitored. Ventilatory and circuit alarms should be adjusted to monitor an appropriate range of V, P and temperature. This should alert adjacent staff to changes in P and/or V that may be caused by an occluded endotracheal tube, tension pneumothorax or circuit disconnection. These alarms may be temporarily disabled while the cause is detected, but never permanently disabled. Sudden difficulties with either high P during volume-preset ventilation or oxygenation must initiate an immediate search for the cause. This should start with the patency of the airway, followed by a structured approach both to the circuit and ventilator, and to factors altering the E and R of the lung and chest wall such as bronchospasm, secretions, pneumothorax and asynchronous breathing. In addition to careful clinical examination, an urgent chest radiograph and bronchoscopy may be required.

Complications of mechanical ventilation

Although mechanical ventilation may be vital, it also introduces numerous potential complications (Box 42.2).[89]

Box 42.2

Complications of intubation and mechanical ventilation[89]

Equipment

- Malfunction or disconnection
- Incorrectly set or prescribed
- Contamination

Pulmonary

- Airway intubation (e.g. damage to teeth, vocal cords and trachea)
- Ventilator-associated pneumonia (reduced lung defence)
- Ventilator-associated lung injury (e.g. diffuse lung injury due to regional overdistension or tidal recruitment of alveoli)
- Overt barotrauma (e.g. pneumothorax)
- O_2 toxicity
- Patient–ventilator asynchrony

Circulation

- ↓ Right ventricular preload →↓ cardiac output
- ↑ Right ventricular afterload (if the lung is overdistended)
- ↓ Splanchnic blood flow with high levels of positive end-expiratory pressure (PEEP) or mean P_{aw}
- ↑ Intra-cranial pressure with high levels of PEEP or mean P_{aw}
- Fluid retention due to ↓ cardiac output →↓ renal blood flow

Other

- Gut distension (air swallowing and hypomotility)
- Mucosal ulceration and bleeding
- Peripheral and respiratory muscle weakness
- Sleep disturbance, agitation and fear (which may be prolonged after recovery)
- Neurocognitive complications

Mechanical ventilation is also associated with a marked increase in the incidence of nosocomial pneumonia due to a reduction in the natural defences of the respiratory tract, and this represents an important advantage offered by NIV. In patients successfully managed with NIV, Girou and colleagues reported a reduction in the incidence of nosocomial pneumonia, associated with improved survival, compared to IV.[119] Erect versus semirecumbent posture[120] also reduces the incidence of ventilator-associated pneumonia.

Whereas lung overdistension may result in alveolar rupture leading to pulmonary interstitial air, pneumomediastinum or pneumothorax, it may also lead to diffuse alveolar damage similar to that found in ARDS. Both are termed VILI, and V_T reduction leads to a marked decrease in ARDS mortality due to a reduction in multiple organ dysfunction (see Chapter 37 - ARDS).[25] Laboratory data suggest that inadequate PEEP with tidal recruitment and derecruitment of alveoli also leads to VILI; however, this has not been proven in a clinical trial. Finally, patient–ventilator asynchrony may result in wasted respiratory work, impaired gas exchange and respiratory distress.

Positive-pressure ventilation elevates intrathoracic pressure, which reduces venous return, right ventricular preload and cardiac output. The impact is reduced by hypervolaemia, and partial-ventilatory support where patient effort and a reduction in pleural pressure augment venous return. Secondary effects include a reduction in regional organ blood flow leading to fluid retention by the kidney, and possibly impaired hepatic function. This latter effect is seen only at high levels of PEEP where an increase in resistance to venous return and a reduction in cardiac output may combine to reduce hepatic blood flow and may also cause stress ulceration.

Sleep disturbance, delirium and discomfort are common in mechanically ventilated patients. These effects may be reduced with analgesia and sedation until weaning is planned; however, it is also important not to prolong mechanical ventilation due to excessive use of sedatives, which may also depress blood pressure and spontaneous respiratory effort. A large clinical trial found no advantage of daily interruption of sedation over continuous infusion of sedation targeted to the lowest effective dose.[121] Both methods offer early mobilisation in ventilated subjects, shorter duration of ventilation, reduced delirium, ICU and hospital length of stay and improved mortality and functional outcomes.[122, 123] However, this direction must be balanced with strategies such as use of neuromuscular blockers in the first 48 hours of mechanical ventilation in ARDS, which reduces mortality,[124] which prevents or reduces asynchronous ventilatory effort. Recently among adults undergoing mechanical ventilation in the ICU, early active mobilisation did not result in a greater number of days alive and out of the hospital than the usual level of mobilisation but was associated with increased adverse events especially in patients with diabetes.[125], [126]

Although pulmonary function has generally recovered by 12 months, complex neurocognitive and physical sequelae persist to at least 5 years in surviving ARDS patients.[127] Cognitive impairment has been associated with hypotension, hypoxaemia and hyperglycaemia. In addition, anxiety, depression and post-traumatic stress disorder are common and appear to be associated with the severity of illness, duration of mechanical ventilation and premorbid factors including depression. All of these issues are increasingly important as improvements in care and greater numbers of patients treated result in more survivors of critical illness. Of particular note, it appears that early interventions can be effective, but that late interventions fail to improve outcomes. For example physical therapy commenced a median of 7 days after initiation of mechanical ventilation for ARF failed to improve long-term physical function,[128] while much earlier intervention in post-surgical patients resulted in improved functional outcomes and reduced length of ICU and hospital stay.[129]

Specific Lung Conditions[130]

Managing Parenchymal Lung Injury (see Chapter 37)

Frequency–tidal volume settings for supporting a patient with parenchymal lung injury must focus on limiting end-inspiratory stretching. The importance of this limitation in improving the outcome has been suggested by several clinical trials.[131], [132] including the NIH ARDS Network trial that showed a 10% absolute reduction in mortality with a ventilator strategy using a pressure <30 cm H_2O and tidal volumes calculated on an ideal body weight of 6 mL/kg compared with 12 mL/kg.[25] As a result, the initial tidal volume settings should begin at a 6-mL/kg ideal body weight. Moreover, strong consideration should be given to further reducing this setting if plateau pressures, adjusted for any effects of excessive chest wall stiffness, exceed 30 cm H_2O. Increases in the tidal volume settings with the use of safe driving pressure[133] might be considered, provided that the subsequent plateau pressure does not exceed 30 cm H_2O. Respiratory rate settings are then adjusted to control the pH. Selection of PEEP is done by assessment of recruitment versus the risk of over-distention in these patients.

Managing Obstructive Airway Disease (see Chapter 47)

Setting the frequency–tidal volume pattern in obstructive lung disease involves many considerations. Unlike parenchymal disease, however, the elevated airway resistance and often low recoil pressures of emphysema greatly increase the potential for PEEPi and air trapping, which limits the higher range of breath rates. Usually, a low respiratory rate and higher tidal volume are set. Tidal volume increase is often considered for comfort or gas exchange, provided that the plateau pressure values do not exceed 30 cm H_2O. The inspiratory-expiratory ratio in obstructive lung disease is set as low as possible to minimise the development of air trapping which means setting a low respiratory rate in these patients.

A judicious application of PEEPe (up to 75% to 85% of PEEPie) can ‘balance’ the expiratory pressure throughout the ventilator circuitry to reduce this triggering load and facilitate the triggering process and decrease the threshold work of breathing.[134, 135]

Managing Normal Lungs (Neuromuscular Injury and the Perioperative Setting)[130]

The risk of VILI is thought to be lower with normal lungs in a mechanically ventilated patient because the lung mechanics are often near normal, making regional overdistention less likely. Use of higher tidal volumes (up to 10 mL/kg IBW) is thus often used to improve comfort, maintain recruitment, and prevent atelectasis. However recent trials in the perioperative setting have demonstrated that limiting plateau pressures and tidal volumes reduces postoperative respiratory complications.[136-138] Regardless of the tidal volume settings, maximal distending pressures should be monitored and kept low while still being compatible with the other goals noted earlier, especially plateau pressure should always be kept well below 30 cm H_2O. Low levels of PEEPe are often beneficial in preventing derecruitment (atelectasis) in these patients, who are often supine and incapable of secretion clearance or spontaneous sigh breaths.

Importantly, in the setting of severe CNS injury and raised intra-cerebral pressure, ventilator setting may require adjustments to the basic lung-protective strategy (lower PEEPe settings and higher minute ventilation) as there are concerns regarding the adverse effects of high intrathoracic pressure and high levels of $PaCO_2$.

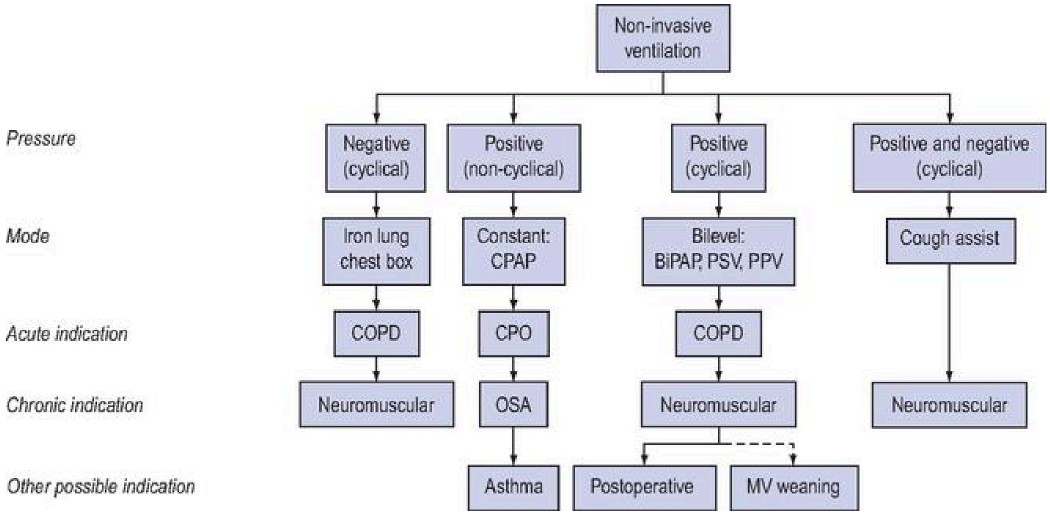
Non-invasive ventilation

Graeme Duke and Andrew Bersten

Non-invasive ventilation (NIV) is a valuable therapeutic option in the management of acute and chronic respiratory failure. For certain diagnoses it is the preferred option[1,2]; for others, the evidence remains controversial as a result of clinician preference, growing demand[3,4] and recent pandemic experience.[5] The history of NIV for acute respiratory failure (ARF) predates the introduction of laryngoscopy and the widespread use of positive-pressure mechanical ventilation (MV) via an endotracheal tube in the 1950s.[2] Clinical success from NIV was first publicised in 1936.[6]

NIV is defined as ventilatory support without (invasive) endotracheal access. It has become standard therapy in the early management of rapidly reversible ARF,[7,8] and in domiciliary management of chronic respiratory failure due to obstructive sleep apnoea (OSA)[9] or neuromuscular disease.[10,11]

NIV may be achieved by applying positive pressure to the airway (P_{ao}) or applying negative pressure to the chest ('chest box' or cuirass) or entire body ('iron lung').[12] A conceptual framework is shown in Fig. 43.1.



Non-invasive ventilation
Pressure
Negative (cyclical)
Positive (non-cyclical)
Positive (cyclical)
Positive and negative (cyclical)
Mode

Constant: CPAP
Bilevel: BiPAP, PSV, PPV
Cough assist
Acute indication
COPD
CPO
COPD
Chronic indication
Neuromuscular
OSA
Neuromuscular
Neuromuscular
Other possible indication
Asthma
Postoperative
MV weaning

The conceptual paradigm categorises non-invasive ventilation into four types based on pressure, that are, negative cyclical, positive non-cyclical, positive cyclical, and positive and negative cyclical. The four types of pressures use a mode each that includes acute, chronic, or other possible indications. Negative cyclical includes an iron lung or chest box used for chronic obstructive pulmonary disease and neuromuscular disorders. Positive non-cyclical uses constant pressure, like continuous positive airway pressure for conditions such as cardiogenic pulmonary oedema, obstructive sleep apnea, and asthma. Positive cyclical pressure includes bilevel modes such as Bi P A P, pressure support ventilation, and positive pressure ventilation used in chronic obstructive pulmonary disease, neuromuscular disorders, postoperative care, and mechanical ventilation weaning. Positive and negative cyclical pressure includes cough assist devices, mainly used in neuromuscular disorders. The diagram aligns each mode with its respective acute, chronic, and other possible indications.

FIG. 43.1 Conceptual non-invasive ventilation paradigm. *BiPAP* , Biphasic positive airway pressure; *CPAP* , continuous positive airway pressure; *COPD* , chronic obstructive pulmonary disease; *CPO* , cardiogenic pulmonary oedema; *MV* , mechanical ventilation; *OSA* , obstructive sleep apnoea; *PPV* , positive-pressure ventilation; *PSV* , pressure support ventilation.

Negative-pressure generators are employed for the management of acute or chronic respiratory disease; however, substantial limitations arise from the induction of OSA, lack of fractional inspired oxygen ($F\text{iO}_2$) control, equipment bulk and size.[13] External negative-pressure generators suit some patients with chronic respiratory failure, particularly as they do not require an oral or nasal prosthesis.

This chapter deals primarily with the use of positive-pressure NIV to treat ARF. Here, the clinical efficacy of NIV depends upon (1) the ventilatory mode selected; (2) the ventilator design and efficiency and (3) the nature and severity of the underlying respiratory pathophysiology. Correctly applied NIV reduces morbidity and mortality,[8,9] whereas incorrect or inappropriate application may delay definitive therapy and adversely affect patient safety and survival. Understanding the physiological rationale for NIV will greatly assist the clinician apply this therapy effectively and minimise its side effects.

Physiology of Non-Invasive Ventilation

The physiological benefits of NIV are similar to those of invasive ventilatory support, discussed in Chapter 42 . NIV can reverse many of the adverse physiological and mechanical derangements associated with ARF, through a combination of:

- augmentation of alveolar ventilation (V_A) to reverse respiratory acidosis and hypercarbia;
- alveolar recruitment and increased $F\text{iO}_2$ to reverse hypoxia;
- reduction in work of breathing (W_{mus}) to reduce respiratory muscle insufficiency;

- mechanical stabilisation of the chest wall in the presence of chest trauma or surgery;
- reduction in left ventricular (LV) afterload that may improve cardiac function [14], [15];
- reduction of right ventricular (RV) afterload and improved RV function.[16]

In brief, the respiratory effort (pressure–volume work[17]) required to achieve a desired minute volume (V_E) may be viewed as the summation of the individual forces that must be overcome to generate inspiratory flow, namely: elastic work (or 'stretch'; W_{el}), flow-resistive work (airflow obstruction; W_{res}) and threshold work-elastic work required to overcome incomplete exhalation leading to gas trapping, persistent inward (elastic) recoil and intrinsic positive end-expiratory pressure (PEEPi). PEEPi and dynamic hyperinflation are absent in the healthy lung but are common in the presence of tachypnoea or expiratory airflow obstruction. During flow limitation, the presence of PEEPi impedes the triggering of inspiratory support modes (inspiratory positive airway pressure [IPAP] and pressure support ventilation [PSV]). Threshold load (PEEPi) must be counterbalanced by additional inspiratory effort before inspiratory flow can commence. External PEEP (CPAP) that matches the magnitude of PEEPi will aid in reducing threshold work. It is important to note that breathing via a circuit will create additional airflow resistance (R) adding to breathing work (W_{mus}), and thus attention to circuit design is important (see later).

Since the volume component is constant the equation of motion can be written as:

$$P_{\mathrm{mus}} = P_{\mathrm{el}} + P_{\mathrm{res}} \qquad \textbf{(42.1)}$$

where P_{mus} is inspiratory respiratory muscle effort, P_{el} is effort required to overcome elastic recoil and P_{res} is effort required to overcome airflow resistance of the respiratory system (see Chapter 38 for a more detailed explanation).

With the addition of a device for ventilatory support, the P_{mus} required by the patient is equivalent to the difference between the applied P_{ao} and the total work required to maintain V_{E} :

$$P_{\mathrm{mus}} = \left(P_{\mathrm{el}} + P_{\mathrm{res}}\right) - P_{\mathrm{ao}} \tag{42.2}$$

This relationship may be rearranged into its individual components, as follows:

$$P_{\mathrm{mus}} + P_{\mathrm{ao}} = E \bullet V + R \bullet \dot{V} + \mathrm{PEEPi} \tag{42.3}$$

where E is the respiratory elastance (inverse of compliance), V is the volume of gas, R is the respiratory and circuit flow resistance, V is the inspiratory flow rate and PEEPi is the intrinsic PEEP. Respiratory failure occurs when the forces opposing inspiration – namely elastic (P_{el}), resistive (P_{res}) and threshold (PEEPi) work – exceed the respiratory muscle effort (P_{mus}) required to maintain V_{E} . Hypermetabolic states (e.g. trauma, sepsis) increase basal V_{E} , whereas pulmonary and chest wall diseases increase respiratory workload and neuromuscular disease impairs respiratory muscle effort. NIV may prevent respiratory failure by counterbalancing the increased respiratory workload and/or reducing respiratory muscle effort, and thus maintain V_{A} .

While any invasive MV mode may be delivered non-invasively, four are commonly described in clinical research: CPAP, PSV, bilevel positive airway pressure (BiPAP) and (pressure- or volume-limited) intermittent positive-pressure ventilation. Other modes under investigation include high frequency for infants and proportional assist ventilation.

All NIV modalities utilise semiclosed or closed circuits and are thus capable of reliably delivering high $F\text{iO}_2$. This is an important mechanism by which NIV improves oxygenation, independently of other mechanisms discussed below.

Continuous Positive Airway Pressure

CPAP is a form of NIV because it provides respiratory support even though the P_{ao} applied is constant throughout the respiratory cycle. This mode addresses a number of the objectives of ventilatory support, namely:

- reduction in the work of breathing by:
    - reduction in alveolar de-recruitment and elastic work
    - reducing threshold load created in the presence of PEEPi
- reversing hypoxia through the delivery of high $F\text{iO}_2$, alveolar recruitment and the reduction of intrapulmonary shunt
- reduction of LV transmural pressure (afterload).[14, 15]

Inspiratory Positive Airway Pressure and Pressure Support Ventilation

Positive inspiratory airway pressure without expiratory pressure (e.g. PSV or IPAP), provides respiratory support by reducing both the elastic and the resistive components of respiratory work resulting in:

- augmentation of tidal volume (V_{E}) and minute volume (V_{E}) and reduction in PaCO_2
- reduction in P_{mus} with diminished risk of respiratory muscle insufficiency
- induction of pulmonary surfactant release through alveolar inflation above resting tidal volume.[17]

BiPAP allows separate settings for inspiratory (IPAP) and expiratory (EPAP) airway pressure levels; it is similar to PSV plus CPAP.[18] Respiratory frequency is usually patient-dependent but may be mechanically time cycled.

Controlled Ventilation

NIV may also be administered as volume- or pressure-limited MV applied via a mask (instead of an endotracheal airway).

Patient–Ventilator Interaction

This is discussed in Chapter 42 and subdivided into: (1) triggering of inspiration, (2) inspiration and (3) cessation of inspiration. Asynchrony is a common cause of NIV failure arising from gas leaks due to poor mask fit.[19] Mask leaks interfere with the ability to sense the end of expiration because there is continued ‘expiratory’ gas flow.

Non-Invasive Ventilation Equipment

Equipment design varies according to NIV mode and purpose (e.g. critical care or domiciliary setting), and significant variations in performance characteristics have been documented.[2,20] The important characteristics of an efficient NIV circuit include:

- High gas flow to match peak inspiratory airflow – high flow rates may be generated by a pressurised gas supply, a gas turbine or a jet venturi mechanism; and a device providing continuous flow imposes less circuit work than a demand flow device
- An expiratory (threshold) resistor capable of maintaining the desired PEEP, yet offering a low resistance to reduce fluctuations in the delivered P_{ao}. This may be a threshold resistor or flow resistor; the optimal position for the expiratory valve is as close to the patient’s airway as possible.
- Short wide-bore tubing to reduce turbulence and flow resistance

- A flow or pressure sensor to identify inspiratory effort and facilitate triggering of the predetermined inspiratory pressure support (e.g. PSV or IPAP)
- Controlled delivery over a wide range of $F\text{iO}_2$
- Other desirable features include humidification, pressure-relief safety valves, battery back-up, apnoea backup support, acoustic suppression and monitoring of volume and P_{ao}. These are important for the management of ARF and less important for domiciliary (long-term) NIV devices.

Several varieties of mask design are now available, and the optimal configuration depends upon the purpose and mode of NIV, patient anatomy and preference. These include intranasal, nasal, oronasal, full-face and helmet (full-head) masks. Desirable features of a mask include lightweight and transparent materials affording a comfortable airtight seal, minimal dead space and separate inspiratory and expiratory ports to minimise airflow turbulence [20] and rebreathing. [21] In lung model studies, expiratory ports over the nasal bridge reduce dead space, [22] which may prove to be clinically advantageous. Orofacial masks have a lower dead space than full-face masks or helmet designs, [23] but a higher risk of air leak. [19]

Mask discomfort, arising from an ill-fitting mask seal, air leaks, humidification or claustrophobia, are common causes of non-compliance. Nasal masks are less reliable at maintaining constant P_{ao} because they are affected by mouth breathing – a common problem in the critically ill patient. Nasal masks are, however, less restrictive on the patient's ability to talk, eat/drink and expectorate and therefore gain higher compliance in long-term and domiciliary applications. To effectively compensate for air leaks, nasal masks should be used with circuits capable of rapidly augmenting and delivering high gas flow (>100 L/min).

Fibreoptic bronchoscopy can be safely performed during NIV, [24], [25] using a full-face mask with at least two ports. One of these can be modified to provide a simple valve for the insertion of the bronchoscope, and the other used for NIV. This technique permits bronchoscopic interventions without intubation even in critically ill patients.

Complications and Assessment of Efficacy

Contraindications and complications specific to NIV are listed in Box 43.1 . Acutely unwell patients requiring NIV should be managed in an area with appropriately trained on-site medical and nursing staff. Although the availability of sophisticated, portable non-invasive ventilators makes it easy to provide NIV in any environment, its benefits may diminish outside the critical care environment. [5, 26]

Box 43.1

Contraindications and complications of non-invasive ventilation

Contraindications

- Respiratory arrest
- Unprotected airway (coma, sedation)
- Upper airway obstruction
- Inability to clear secretions
- Untreated pneumothorax
- Marked haemodynamic instability

Complications

- Mask discomfort, patient intolerance
- Facial or ocular abrasions
- Nasal congestion, sinus pain
- Oronasal dryness
- ↑ Intraocular pressure (particularly in patients with glaucoma)
- ↑ Intracranial pressure (particularly in patients with neurotrauma)
- ↓ Blood pressure (if hypovolaemic)
- Aspiration pneumonia (rare)

- Aerophagy and gastric distension (uncommon; routine gastric decompression is unnecessary)

The reversal of hypoxia and/or a subjective reduction in respiratory effort is commonly observed upon commencement of NIV, yet they are a poor guide to its efficacy. More reliable clinical measures of NIV efficacy include the reversal of hypercarbia, a sustained improvement in respiratory function and objective outcomes, such as a reduction in intubation, nosocomial pneumonia and mortality.

Non-Invasive Ventilation and Acute Respiratory Failure

Cardiogenic Pulmonary Oedema

Acute cardiogenic pulmonary oedema (CPO) is a common cause of severe reversible ARF. Since the 1930s, the therapeutic benefits of all modes of NIV have been documented.[7, 27, 28] CPO leads to an increase in elastic workload (P_{el}) and, to a lesser extent, resistive workload (P_{res}), an increase in lung water and impaired surfactant function. CPAP reverses hypoxia, supports EELV and alveolar recruitment and reduces intrapulmonary shunt; reduces transmural pressure and LV afterload. The redistribution of extravascular lung water from the alveoli to the interstitial space is aided by recruitment and improved surfactant function.

Over 20 prospective, randomised, controlled trials of NIV in CPO have demonstrated physiological improvements in hypoxic and hypercapnic respiratory failure, and a significant reduction in the need for intubation (relative risk 95% confidence interval [RR 95% CI] = 0.38–0.62), duration of respiratory support, hospital length of stay and improved survival (RR 95% CI = 0.51−0.82).[7] The number of treated patients needed to avoid one intubation or death has been estimated at 13 and 17, respectively.

NIV should be considered standard therapy for CPO. The optimal mode of NIV and optimal P_{ao} level remains unresolved, although 10 cm H_2O

CPAP appeared to be safe and effective and well supported by evidence.[7,27] The addition of a differential inspiratory pressure (e.g. IPAP and PSV) may be as effective but does not appear to have any benefit over CPAP alone.[29,30] CPAP reduces preload and afterload and myocardial catecholamine release,[31] whereas the cyclical P_{ao} (of bilevel NIV) may cause fluctuation in the LV afterload during the respiratory cycle.

Acute Respiratory Failure in Chronic Obstructive Pulmonary Disease

Reversible ARF is a common complication of chronic obstructive pulmonary disease (COPD). These patients have an elevated resistive work (P_{res}), often coupled with an elevated basal V_E and elastic work (P_{el}) as a result of the pre-existing parenchymal damage. Threshold load (PEEPi) is frequently present as a consequence of airflow obstruction, and is exacerbated by the increase in respiratory rate and P_{res} .

The benefits of NIV in hypercapnic ARF are now supported by at least 17 well-performed prospective, randomised, controlled studies[8,27] in more than 1200 patients. Most investigators reported a low prevalence of side effects and a significant decrease in intubation rates and in-hospital mortality. A meta-analysis of NIV trials reveals significant reductions in mortality (95% CI, RR = 0.38–0.76) and the need for intubation (95% CI, RR = 0.28-0.46) – the estimated number of treatment patients needed to avoid one intubation or death being as few as 5 and 12, respectively.[8] Risk reduction appears to be proportional to the severity of respiratory acidosis. The incidence of nosocomial pneumonia is lower with NIV,[32] and this may explain some of the survival benefits associated with NIV.

All modes of NIV appear to be beneficial, but the optimal mode and pressure settings remain unresolved.[27] Patients with ARF arising predominantly from reversible airflow obstruction (P_{res}) with increased threshold and resistive load are likely to respond to CPAP, taking care not to exceed the level of threshold load. Hypercapnic patients experiencing reduced alveolar ventilation and respiratory muscle insufficiency are likely to benefit from the addition of inspiratory (PSV or IPAP) support, with the trigger set to the lowest possible setting without auto-cycling.

A trial of NIV is indicated by the presence of respiratory acidosis (pH <7.37) or persistent breathlessness.[27] It is poorly tolerated in those with mild impairment or without acidosis; in this setting the small additional circuit load may, paradoxically, increase respiratory work.

Inspiratory support (starting at a low level of 4–6 cm H_2O) should be titrated to improve V_E as indicated by (1) an improvement in exhaled tidal volume and arterial pH, and (2) a reduction in respiratory rate and/or PaCO_2. Low levels of CPAP or EPAP (4–8 cm H_2O) are usually required to counterbalance threshold load and trigger the ventilator to cycle from expiratory to inspiratory support. Clinical observation and judgement are required to titrate CPAP (or EPAP) to a level that minimises the respiratory effort required to trigger inspiratory support (PSV or IPAP). $F\mathrm{iO}_2$ is titrated to reverse hypoxia.

Early predictors of NIV success in COPD patients include improvements in arterial pH and PaCO_2 (but not PaO_2) within the first 1–2 hours of therapy.[32, 33] Predictors of NIV failure include persistent mask intolerance, worsening acidosis (pH <7.25), rising PaCO_2, persistent tachypnoea (>35/min) or increased somnolence. The bedside plan should clearly address the clinical indications and response should the trial of NIV fail. Mask intolerance, nursing workload and failure rates are greater (>30%) during NIV for COPD than those reported in CPO. These patients benefit from a critical care setting where expertise and equipment are available, and where reported outcomes appear better.

While reported success rates are high (70%–90%), NIV failure (requiring intubation) appears to increase with the severity of respiratory acidosis. For the poorly compliant patient, reassurance and explanation together with a trial of different mask sizes and/or types and initiation with low-pressure settings, plus brief periods off NIV will sometimes assist. Repeated reassurance and judicious use of low-dose anxiolytic agents may be beneficial but should be used with caution.

Late failure (>48 hours) occurs in 10%–20% of patients[27, 32, 33] despite an initial improvement with NIV therapy. This group of patients has a high mortality risk. Whether this reflects the severity of the underlying disease, or the delayed initiation of invasive respiratory support (MV) remains unclear.

Asthma

Asthma is an acute inflammatory lung disease that increases resistive (P_{res}) and threshold (PEEPi) respiratory work. Clinical improvement[34–38] and physiological improvement have been demonstrated in severe asthma following the application of CPAP or bilevel NIV.

The role of NIV in the management of acute asthma, and the optimal mode and pressure settings, remain to be clarified. Nebulised therapeutic agents can be effectively delivered even in the presence of a high-flow NIV circuit.[39] Avoid the use of nebulised saline which itself is a bronchoconstrictor.[40] Controlled clinical studies with robust endpoints are awaited. Low-level CPAP (5 cm H_2O) may be effective in moderate to severe asthma unresponsive to steroids and continuous inhaled bronchodilators. Mask intolerance due to anxiety is the most frequent cause of NIV failure. Therefore NIV should be delivered in a high-acuity environment with appropriately skilled staff where those who fail can safely undergo urgent intubation.

Acute Respiratory Distress Syndrome

Like CPO, acute respiratory distress syndrome (ARDS) leads to an increase in elastic workload (P_{el}) and, to a lesser extent, resistive workload (P_{res}) arising from an increase in alveolar–capillary permeability, the release of inflammatory mediators and impaired surfactant function. In contrast to CPO, current data do not support the routine use of NIV in ARDS, non-cardiogenic or undifferentiated, hypoxaemic ARF.[27, 41]

Despite numerous case reports of successful NIV in the setting of community-acquired pneumonia and other forms of ARDS, the failure rate associated with NIV remains high.[42, 43] This may reflect the differences in duration, severity and pathophysiology in pneumonia and ARDS in contrast to CPO. Apparent benefit in published reports may be due to the inclusion of subjects with concomitant CPO or COPD – those subgroups that benefit from NIV.

Pneumonia in the Immunocompromised Patient

Intubation and MV are associated with high morbidity and mortality in immunocompromised patients with hypoxic respiratory failure.[44–47] These patients may benefit from an early trial NIV, although evidence for improved survival in large randomised trials is lacking.[48] Whether NIV benefits this group by reducing unnecessary exposure to a high-morbidity (intubation and MV[49]) therapy or by identifying responders (with rapidly reversible ARF) remains unclear. It seems reasonable, based on the current evidence, to offer NIV to these patients[27] with a clear escalation plan for patient management should the trial of NIV fail. As early bronchoscopic sampling is often key to diagnosis and management, the choice between early intubation and ventilation or a trial of NIV should be influenced by local expertise in performing bronchoscopy during NIV.

Postoperative and Post-Traumatic Acute Respiratory Failure

ARF in postoperative and trauma patients may arise from a number of reversible pathological processes associated with increases in elastic workload (P_{el}) and impaired respiratory muscle function (P_{mus}), including dependent atelectasis, impaired chest wall mechanics, poor cough, nosocomial infection, aspiration pneumonitis and non-respiratory trauma or sepsis.

Mask CPAP consistently improves clinical signs (e.g. oxygenation and respiratory rate) and may reduce the risk of intubation in general surgical[50] and cardiothoracic patients[51–53] with mild postoperative hypoxic respiratory failure or associated COPD, but evidence for a survival benefit is lacking to support routine use[27] and unusually high rates of failure are reported in the control groups.

Mask CPAP has been shown to be superior to MV in patients with isolated severe chest trauma,[54],[55] and the benefit of adding PSV remains unclear. NIV is contraindicated in the presence of neurotrauma, intracranial hypertension, facial trauma or the presence of an undrained acute pneumothorax.

Non-Invasive Ventilation-Assisted Weaning

Since NIV is effective in reducing the need for intubation, it has been postulated that NIV may facilitate early extubation[56] and reduce the risk of failed (planned or accidental) extubation.[57]

NIV following early extubation in COPD patients appears to posit a survival benefit,[58],[59] but it cannot be recommended in the non-COPD group where reported failure (reintubation) rates are unacceptably high,[60] NIV offers no benefit[23] and mortality risk may be higher. NIV provides post-extubation rescue therapy for COPD patients, but it is not a substitute for weaning strategies that reduce the risk of extubation failure. Other causes of hypercapnia including neuromuscular disease, obesity hypoventilation syndrome and severe OSA should also be considered for post-extubation NIV.

High-Flow IntraNasal Oxygen Therapy

High-flow intranasal oxygen therapy (HFNO) systems deliver humidified oxygen at high flows (up to 60 L/min) via nasal cannula, with or without a pressure seal. Humidification improves patient tolerance and high flows create low levels of CPAP in the hypopharynx, reduce dead space and improve lung volumes.[61] This form of therapy is useful in neonates. Its benefits and role in adult ARF are less clear. HFNO consistently improves oxygenation, but failure (intubation) is frequent and improved survival remains controversial.[62]

Non-Invasive Ventilation During Respiratory Viral Pandemic

Several highly contagious respiratory viruses associated with seasonal epidemic or pandemic hypoxaemic ARF, notably coronaviruses (SARS CoV-1 [63] and COVID-19, [5, 64] Middle Eastern Respiratory Syndrome [65]) and influenza A (H1N1) [66] have prompted clinicians to consider NIV as desirable, if not first-line, therapy. Its role remains controversial. NIV is associated with improved oxygenation and may reduce the need for intubation. [67, 68] In contrast, the results of several large controlled trials of bilevel NIV in COVID-19 have demonstrated a high failure rate (50%–75%) and the absence of overall survival benefit compared to high-flow nasal cannula or intubation and MV in mild and severe cases, respectively. [64–68] Whether this is due to the absence of therapeutic benefit, increased risk of patient-induced lung injury and volutrauma or delayed intubation, remains unclear. In the setting of high demand and resource constraints, however, it would appear reasonable to consider a trial of NIV [5] in association with a clear strategy to manage the high failure risk. All high-flow devices pose a risk for respiratory viral transmission to staff if the relevant infection control and personal protective equipment are not employed.

Non-Invasive Ventilation and Sleep Apnoea Syndromes

Moderate or severe OSA results in nocturnal hypoventilation and episodic hypoxia that can lead to pulmonary and systemic hypertension, cardiac failure, plus daytime hypercapnia and somnolence. [9] Many of these complications can be reversed through the appropriate use of nocturnal CPAP. [69–71] Patients with suspected sleep apnoea require accurate assessment by a respiratory physician, including sleep studies, prior to the routine use of domiciliary CPAP. Bilevel or controlled ventilation is required when there is inadequate central respiratory drive or increased elastic work. [9] In many patients, respiratory drive will improve and can be managed, after a period of bilevel or controlled ventilation, with CPAP alone.

Intercurrent illness, surgery or the use of sedatives and opioid analgesics, will increase the frequency and duration of hypopnoea, apnoea and hypoxia. CPAP is beneficial even for those patients who do not require admission to a critical care ward.

Non-Invasive Ventilation and Chronic Respiratory Disease

NIV is an important modality for the long-term treatment of severe chronic hypoventilation syndromes associated with extrapulmonary diseases, such as neuromuscular disease,[10,11] thoracic deformities,[72] COPD with hypercapnia,[73] and cystic fibrosis (CF).[74,75]

These patients may require short-term respiratory support during an acute illness or as an aid to perioperative care in a critical care environment. NIV (with or without cough-assistance devices[76]) may improve outcomes compared with intubation and MV,[77,78] but failure rates appear to be higher. Diagnosis of these underlying disorders during admission for the treatment of severe ARF should prompt referral and assessment for long-term NIV.

Non-Invasive Ventilation and Chronic Hypoventilation Syndromes

Domiciliary NIV (predominantly using inspiratory support modes or NIPPV) should be considered in all patients with severe chronic respiratory failure due to neuromuscular disease.[10,11,77] Early referral and consideration of domiciliary NIV are recommended because of improved outcomes and quality of life.[73–77]

Assessment of these patients for domiciliary NIV includes respiratory function tests, blood gas analysis and sleep studies, together with trials of NIV modes and pressure settings. In general, indications for long-term NIV include the demonstration of symptomatic respiratory failure, daytime hypercapnia and a significantly reduced (<20% predicted) vital capacity. The use of nocturnal or intermittent NIV has been shown to improve daytime respiratory and cardiac function,[70] to improve exercise endurance, to slow the progression of respiratory dysfunction and to reduce the frequency of hospitalisation.[74,79]

Airway management and acute airway obstruction

Gordon YS Choi and Gavin Matthew Joynt

The primary objective of airway management is to clear or bypass the obstructed airway and protect the lungs from soiling. Acute upper airway obstruction is a life-threatening emergency, resulting from a wide range of pathophysiological processes. Rapid assessment and establishment of a patent airway are vital, often in the absence of a specific diagnosis. As no single airway management modality is universally applicable, the intensive care unit (ICU) physician must be capable of performing a variety of airway management techniques (Fig. 44.1).

* Consider maintaining spontaneous breathing

** Call for help and consider allowing patient to wake up if immediate intubation is not essential

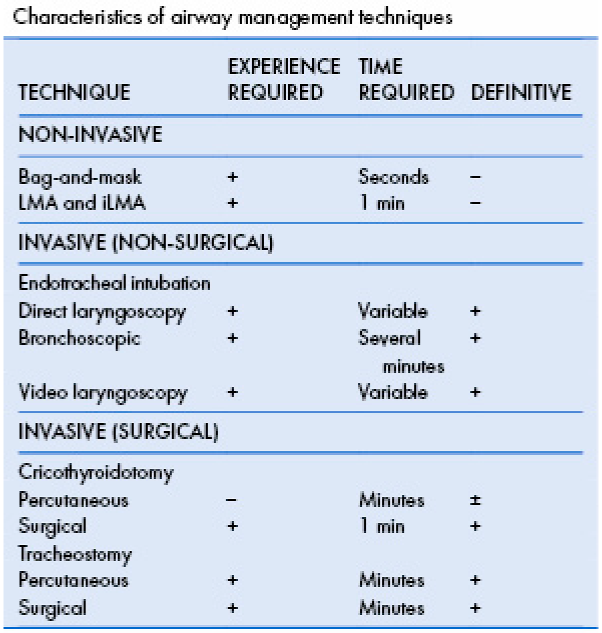
The flowchart depicts the decision to intubate trachea, representing pathways based on anticipated or no anticipated difficulty. If difficulty is anticipated, it branches based on whether the patient is cooperative. For a cooperative patient, options include awake intubation or elective surgery airway. If the patient is uncooperative or has minimal spontaneous breathing, the chart advises intravenous anaesthetic and paralysis, followed by intubation choices such as a video laryngoscope or fiberoptic bronchoscope. If intubation fails, a supraglottic airway or emergency surgical airway is indicated. For unanticipated difficulty, initial intubation attempts may succeed or fail, prompting the use of supraglottic airways or front-of-neck access. Success or failure paths are clearly marked at each decision point, ending in either conformation or intubation or cricothyrotomy.

FIG. 44.1 Difficult airway algorithm. Hypoxia may develop rapidly in ICU patients, and when hypoxia occurs, and the application of less invasive solutions is not immediately successful, eFONA should not be delayed. *iLMA* , Intubating laryngeal mask airway; *IV* , intravenous; *LA* , local anaesthetic; *LMA* , laryngeal mask airway; eFONA, emergency front of neck access.

Airway Management Techniques

Airway management techniques can be considered non-invasive or invasive, depending on whether instrumentation occurs above or below the glottis, and is surgical or non-surgical (Table 44.1). Definitive techniques secure the trachea and provide some protection from macroscopic aspiration and soiling. Although most airway management in the ICU is still achieved by bag-and-mask ventilation and direct or video laryngoscopic tracheal intubation, the use of fibreoptic bronchoscopy is a necessary skill, especially in special circumstances. Management of failed intubation and ventilation by utilising various alternative techniques (e.g. laryngeal mask airway [LMA] and cricothyroidotomy) is now well described.[1,2]

Table 44.1



Characteristics of airway management techniques

TECHNIQUE	EXPERIENCE REQUIRED	TIME REQUIRED	DEFINITIVE
NON-INVASIVE			
Bag-and-mask	+	Seconds	–
LMA and iLMA	+	1 min	–
INVASIVE (NON-SURGICAL)

Surgical	+	1 min	+
Tracheostomy			
Percutaneous	+	Minutes	+
Surgical	+	Minutes	+

iLMA , Intubating laryngeal mask airway; *LMA* , laryngeal mask airway.

The technique of choice will depend on each situation and is a consequence of the interaction of patient factors and the clinician's experience (Table 44.2). Other factors include availability of help, levels of training and supervision and accessibility of equipment. A portable storage unit with a wide choice of equipment appropriate for difficult airway management is necessary in the ICU (Box 44.1).

Table 44.2

Application of airway management techniques

	DIFFICULT DIRECT LARYNGOSCOPIC INTUBATION	DIFFICULT SPONTANEOUS/MASK VENTILATION
Awake	Fibreoptic bronchoscopic intubation	Percutaneous cricothyroidotomy [a] Surgical tracheostomy [a]
Anaesthetised or comatose (empty stomach)	Bag-and-mask ventilation Direct laryngoscopic intubation Different blade choices Video laryngoscopy Fibreoptic bronchoscopic intubation Intubating LMA/LMA	Laryngeal mask airway Percutaneous cricothyroidotomy Surgical tracheostomy
Anaesthetised or comatose (full stomach)	Consider cricoid pressure Consider ProSeal LMA	Percutaneous cricothyroidotomy Surgical tracheostomy

[a] Under local anaesthesia.

LMA , Laryngeal mask airway.

Examples of common alternatives are given. The technique chosen will depend on clinician’s preference.

Box 44.1

Suggested contents of a portable storage facility for difficult airway management

- Masks
    - Face and nasal masks of differing make and size variety
- Airways
    - Oropharyngeal airways
    - Nasopharyngeal airways
    - Laryngeal mask airway (LMA) and intubating LMA with appropriate endotracheal tubes
- Rigid laryngoscope with a variety of designs and sizes
    - Short handle or variable angle (Patil–Syracuse) laryngoscope
    - Curved blades: Macintosh, Bizzarri–Giuffrida
    - Straight blades: Miller
    - Bent blades: Belscope
    - Articulating tip blades: McCoy
- Video-laryngoscope
    - Disposable
    - Non-disposable
- Endotracheal tubes of assorted size
    - Murphy tubes
    - Microlaryngoscopy tubes
- Endotracheal tube stylets
    - Bougie
    - Malleable stylet
    - Tube changer, hollow tube changer
- Fibreoptic intubation equipment
    - Patil endoscopic mask for oral endoscopic intubation
    - Fibreoptic endoscopes with a light source, adult and paediatric-sized
- Front of Neck Access (FONA)
    - Percutaneous cricothyroidotomy set (Seldinger or trocar type)
    - Scalpel-bougie set
- Exhaled carbon dioxide monitor
    - Capnometer/capnograph
    - Chemical indicators

Non-Invasive Techniques

Bag-Mask Ventilation

As with most airway management techniques, mask ventilation is a basic skill that requires time and experience to master. It should be learned using manikins, simulators and practiced in the controlled environment of the operating theatre so that when used in the emergency setting in the ICU the skill is well established. The bag may be a self-inflating resuscitator or one attached to an anaesthetic circuit. Most resuscitators require a reservoir bag in series with a self-inflating bag that ensures a high oxygen concentration can be delivered. The addition of positive end-expiratory pressure (PEEP) may improve arterial oxygenation and overcome airway obstruction due to laryngospasm.

Some considerations when performing mask ventilation include the following:

- *Inadequate ventilation:* the seal of the mask against the face may be inadequate and good hand positioning is essential. Ventilation of edentulous patients may be aided by improving hand position or special masks. Two operators are recommended if a mask face leak is excessive: one to hold the mask and the other to manipulate the bag-mask resuscitator.
- *Hyperventilation:* unnecessary hyperventilation may occasionally cause dynamic pulmonary hyperinflation and cardiovascular compromise.
- *Gastric insufflation:* this increases the risk of vomiting and aspiration. Carefully applied cricoid pressure may prevent gastric gas insufflation.
- *Pulmonary aspiration:* in an emergency situation with a full stomach, mask ventilation with cricoid pressure may be necessary until the airway can be secured. Passage of a nasogastric tube to aspirate gastric contents may be successful, but emptying cannot be guaranteed and vomiting may be induced.

Oro- and Nasopharyngeal Airways

In the unconscious patient, functional obstruction may occur because of loss of muscular tone and inspiratory airway narrowing at the soft palate, epiglottis and tongue base. An oropharyngeal airway device may establish an adequate airway for spontaneous or bag-mask ventilation when proper head positioning is insufficient. Complications include mucosal trauma, worsening the obstruction by pressing the epiglottis against the laryngeal outlet if the tongue displaces posteriorly, and occasionally laryngospasm. The following sizes (length from flange to tip) are recommended: large adult: 100 mm (Guedel size 5), medium adult: 90 mm (Guedel size 4) and small adult: 80 mm (Guedel size 3).

A nasopharyngeal airway is a soft rubber or plastic tube inserted into the nostril and advanced along the floor of the nose (in the direction of the occiput). It is better tolerated by semiconscious patients than the oropharyngeal airway. Complications include epistaxis, aspiration and, rarely, laryngospasm and oesophageal placement.

Supraglottic Airways

The original LMA is a reusable device that consists of a silicone rubber tube connected to a distal elliptical spoon-shaped mask with an inflatable rim, which is positioned blindly into the pharynx to form a low-pressure seal against the laryngeal inlet. [3] There are a variety of sizes for use in children and adults. LMAs are useful to achieve non-definitive airway patency in many emergency situations (see Fig. 44.1), and can be used to provide limited positive-pressure ventilation.

Once positioned, the LMA can be used to guide the passage of stylets, bougies, the bronchoscope or even an endotracheal tube into the trachea. The intubating LMA (FasTrach) is a modification of the LMA with several features to facilitate intubation once the LMA is placed. There is a guiding ramp and epiglottic elevating bar at the aperture to direct the endotracheal tube to the glottis. It also has an anatomically curved, rigid shaft and handle to allow easy and firm manipulation during placement and when the endotracheal tube is passed. The successful use of LMA requires some familiarity with the equipment and technique, and at least simulated exposure is strongly recommended. Second-generation LMAs have additional advantageous features such as higher seal pressure, facilitate easy passage of a tube for gastric decompression, and allow improved conditions for fibre-optically guided tracheal intubation.[4] Examples include the i-gel (Intersurgical, Wokingham, United Kingdom), the Proseal LMA (PLMA; Teleflex Medical Europe Ltd, Athlone, Ireland) and the LMA Supreme (SLMA; Teleflex Medical Ltd). Differences in clinical performance between the second-generation devices are generally small.[5], [6]

Contraindications for using the LMA include inability to open the mouth, pharyngeal pathology, airway obstruction at or below the larynx, low pulmonary compliance or high airway resistance. Complications include aspiration, gastric insufflation, partial airway obstruction, coughing, laryngospasm, post-extubation stridor and kinking of the shaft of the LMA.

Invasive Techniques

Endotracheal Intubation

Endotracheal intubation remains the gold standard airway management technique, allowing for spontaneous and positive-pressure ventilation, with good macroscopic protection from aspiration. Indications include acute airway obstruction, facilitation of tracheal suctioning, protection of the airway in those without protective reflexes and respiratory failure requiring ventilatory support with high inspired concentrations of oxygen and PEEP.

Prior to proceeding with an intubation attempt, regardless of the technique chosen, pre-oxygenation, as well as preparation and checking of all relevant equipment, is essential. It is recommended that the operator has a defined initial intubation plan (Plan A), and sequential alternative plans (Plans B, C and D) should intubation difficulty arise.[7] These plans may be based on the flowchart provided (see Fig. 44.1) and the various common techniques available (see Table 44.2). A pre-intubation checklist should be available to ensure all necessary intubating equipment is immediately available. Pre-oxygenation may be improved by the provision of 100% oxygen using non-invasive ventilation (NIV), or high-flow nasal cannula (HFNC), although a clear advantage of one method over the other has not been shown.[8] When comparing NIV directly with HFNC for pre-oxygenation, hypoxaemia occurred less frequently after pre-oxygenation with NIV than with HFNC; however, serious adverse events did not differ between the groups. [9] Recently, bag-mask ventilation between induction and laryngoscopy compared with no ventilation was shown to reduce severe episodes of hypoxaemia, without increasing the rate of aspiration. [10]

Additional difficult airway management equipment required for implementing relevant alternative intubation plans (see Box 44.1) should also be rapidly accessible, usually in the form of a mobile difficult intubation trolley. Food, vomitus, blood or sputum may obstruct the airway and suction should always be available. Suction apparatus should generate at least 300 mm Hg (40 kPa) and 30 L/min. Excessively vigorous suctioning should be avoided, as it can cause laryngospasm, vagal stimulation, mucosal injury and bleeding.

Direct laryngoscopy

Although essential for all intensivists, direct laryngoscopy is a difficult skill to master. [11] If multiple intubation attempts are required, the maximum interruption to ventilation should be about 30 seconds. Adequate ventilation and oxygenation must be provided between attempts. Minimum monitoring should consist of continuous-pulse oximetry, end-tidal CO_2, electrocardiogram (ECG) and blood pressure. The backward, upward, rightward pressure (BURP) technique may be helpful to bring the vocal cords into the field of vision. Endotracheal tube size describes the internal diameter and, where possible, 8.0–9.0 mm in adult males and 7.5–8.0 mm in adult females are generally used to facilitate sputum clearance, minimise airway resistance and allow access for fibreoptic bronchoscopy. Special-purpose tubes include double-lumen tubes to facilitate lung isolation, laser-resistant tubes and those that allow sub-glottic suction. Spiral wire reinforced endotracheal tubes, or ‘armoured’ tubes provide added resistance against kinking when bent and are useful for supporting certain surgical procedures; however, when deformed, for example by biting from a conscious patient, they hold the deformed shape, and this may cause dangerous intra-luminal restriction. Therefore controlled exchange for a standard endotracheal tube is recommended prior to, or immediately upon ICU admission.

The orotracheal route is generally recommended because it may be associated with fewer complications.[12] However, nasotracheal intubation allows easier tube fixation and avoids the risk of tube occlusion from biting, and is more commonly used in paediatric patients. Nasotracheal intubation is contraindicated in the presence of fracture of the base of the skull and complications include epistaxis, turbinate cartilage and nasal septal damage during insertion.

Bougie introducer and stylet guide

The ‘anterior larynx’ can often be more easily intubated if a bougie is advanced in the midline and directed anteriorly into the trachea. The endotracheal tube is then advanced over the bougie. Clinical signs of correct tracheal placement of the guide include coughing, resistance felt before the guide is fully advanced (usually at 45 cm or less from the lips because of resistance at the carina or bronchus) and a sensation of clicks from the tracheal rings. Alternative intubating guides are available, including the hollow endotracheal tube changer, which can be attached to a side-stream capnometer, or to an oxygen source. The stylet guide is a malleable rod, usually encased in plastic, that is placed within the endotracheal tube lumen and used to adjust the curve of the endotracheal tube to make insertion easier when using a laryngoscope or video-laryngoscope.

Video laryngoscopy

The video-laryngoscope (VL) is a device that transmits a view of the glottis from near the laryngoscope tip onto a small proximal screen. When used for difficult airway management, VLs produce similar or better intubation success rates compared with direct laryngoscopy and reduce cervical spine movement during laryngoscopy.[13] Comparisons between VLs and the traditional laryngoscope for routine use for intubation in ICU have demonstrated superior first-pass intubation success rates for VL, but no reduction in serious complications associated with intubation.[14] Glottic visualisation appears better with VL techniques; however, placement of the endotracheal tube may be more challenging. Limitations do exist for each particular device, and both training and operator experience contribute to successful use. In summary, VL is increasingly available and does offer advantages such as a higher rate of first-pass intubation rates and improved novice intubating performance, but improvements in intubation safety have not yet been consistently shown. Operators should choose the technique best matched to their skills and the operating environment. [14], [15]

Fibreoptic bronchoscopic technique

This technique is less commonly used but offers advantages of direct visualisation, immediate diagnosis of upper airway lesions and immobility of the neck during the procedure. It is most useful in patients with abnormal airway anatomy, and limited jaw or neck mobility, e.g. chronic nasopharyngeal carcinoma. It also allows reasonably comfortable intubation of a cooperative, awake patient under local anaesthesia and use of the sitting position. Experience and skill are necessary, especially for dealing with emergent situations, but success rates greater than 96% are expected. [16] A number of specially designed oral airways are available to assist oral fibreoptic intubation (e.g. the Ovassapian, Williams or Berman airway). Oral or nasal intubation is usually performed by guiding an endotracheal tube placed over the bronchoscope, with the tip of the bronchoscope positioned just above the glottis. The fibreoptic bronchoscope tip is guided into the trachea and the tube is advanced over the bronchoscope. Correct placement is visually checked before the scope is removed. In ICU, the fibreoptic bronchoscope can be used to improve the safety of airway procedures such as endotracheal tube changes and percutaneous tracheostomy. [17] The most common cause of failure is obstructed vision from blood or secretions.

Confirmation of tracheal tube placement

Confirmation of correct intratracheal tube placement is essential. Direct visualisation and measurement of expired CO_2 by capnography are the most reliable methods. [18] Capnography may produce false-positive results with the first few breaths after oesophageal intubation (i.e. detectable $\mathrm{PE}_{\mathrm{CO_2}}$), if gastric insufflation from mask ventilation has occurred. A false-negative (decreased $\mathrm{PE}_{\mathrm{CO_2}}$, despite correct position) may occur with cardiac arrest and low-cardiac-output states. Other clinical signs, such as auscultation for breath sounds over both sides of the chest and epigastrium, visualisation of condensed water vapour in the tube and chest wall movement are less reliable. The use of capnography is further discussed in Chapter 38 .

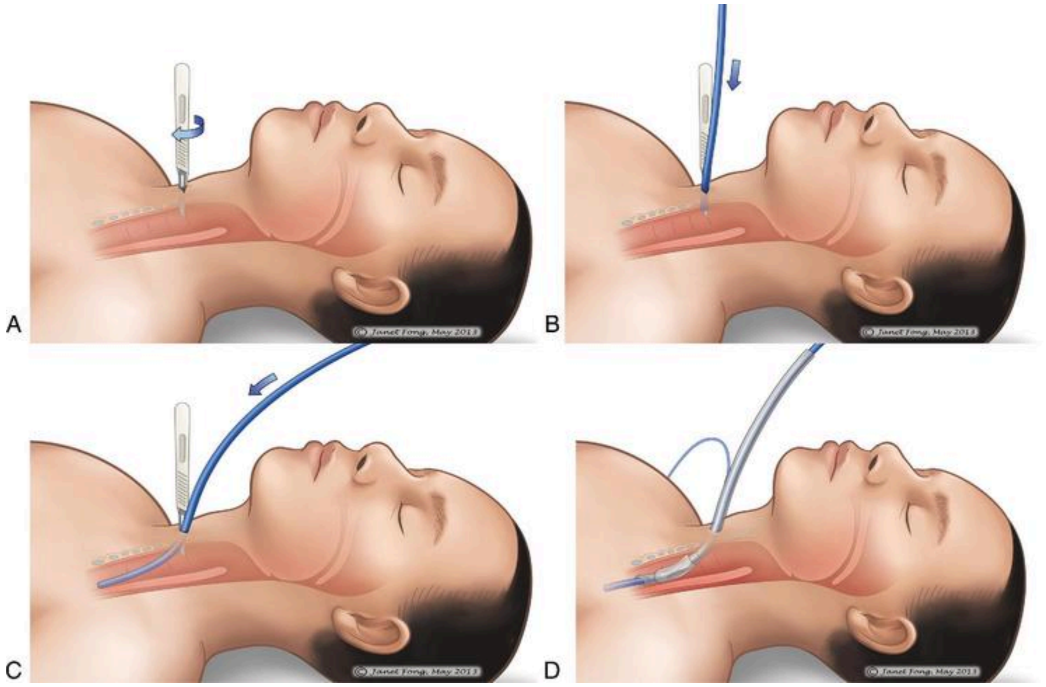
Complications of endotracheal intubation

These may be classified into those occurring during intubation (e.g. incorrect tube placement, laryngeal trauma, deleterious cardiovascular response to laryngoscopy and intubation, increase in intracranial pressure, hypoxaemia and aspiration), while the tube is in place (e.g. blockage, dislodgement, tube deformation, damage to larynx and complications of mechanical ventilation), and following extubation (e.g. aspiration and post-extubation airway obstruction, laryngeal and tracheal stenosis). As few ICU patients can be adequately starved prior to intubation, the use of cricoid pressure, provided it does not obscure the glottic view, may be considered. Hypotension in ICU patients is common immediately following intubation because of drug-induced myocardial depression, decrease in peripheral vascular resistance and sympathetic stimulation, and reduced venous return after positive-pressure ventilation. A recent multicentre observational study revealed that cardiovascular instability was observed to be the most common adverse event during the peri-intubation period.[19] While a recent study demonstrated that the routine infusion of a moderate fluid bolus (up to 500 mL) prior to intubation in ICU adult patients did not reduce the risk of severe cardiovascular compromise,[20] fluid administration in potentially hypovolaemic patients and/or the use of vasopressor drugs are often required to offset the hypotensive effects of drugs used to facilitate intubation, changes in autonomic nervous balance, and the physical effects of positive-pressure ventilation. Special techniques should be used to minimise side effects such as cardiovascular responses and increases in intracranial pressure, when appropriate.

Emergency Front of Neck Access (eFONA)

Cricothyroidotomy is a reliable, relatively easy way of providing an emergency airway.[21] It is the method of choice if severe or complete upper airway obstruction exists. Two cricothyroidotomy techniques are recommended.

Scalpel cricothyroidotomy is the simplest, fastest and most proven method that uses a horizontal incision through the cricothyroid membrane (with the space held wide open by the scalpel handle, forceps or a tracheal hook), followed by insertion of a small tracheal tube. ‘Bougie-assisted cricothyroidotomy’ utilises a bougie to secure the passage into the trachea, and the bougie is used to guide the tracheal tube into place (Fig. 44.2).



The diagram of the four-step percutaneous tracheostomy procedure is depicted in four parts, labelled A to D. Part A shows a needle inserted through the neck into the trachea. Part B depicts a guidewire passing through the needle into the trachea. Part C depicts a dilator inserted over the guidewire to enlarge the opening. Part D depicts a tracheostomy tube placed through the dilated tract into the trachea, with the guidewire and dilator removed. The head and neck remain extended in all parts, and the trachea is visible in cross-section with the instruments passing through the anterior neck into the airway.

FIG. 44.2 Bougie assisted with cricothyroidotomy. (A) Perform a horizontal incision through the cricothyroid membrane and rotate the blade so that it faces caudally, (B) with the space held open by the scalpel blade, insert a bougie, (C) advance the bougie caudally into the trachea and (D) the bougie is used to guide the tracheal tube into place.

Percutaneous cannula cricothyroidotomy is an alternative method. Different commercial devices exist, but all require puncture of the cricothyroid membrane either by a needle (utilising the Seldinger technique to guide a cannula into position over a guidewire) or trocar that allows a cannula to be directly placed in position by sliding it over the trocar.

A cannula with an internal diameter of ≥ 3.0 mm will allow adequate gas flow for self-inflating bag ventilation provided supplemental oxygen is used. Since the diameter of the cricothyroid space is 9 by 30 mm, tubes of 8.5 mm outer diameter or less should avoid laryngeal and vocal cord damage. Complications such as subglottic stenosis (1.6%), thyroid fracture, haemorrhage and pneumothorax are acceptably low. Cricothyroidotomy is generally contraindicated in complete laryngotracheal disruption and age less than 12 years.

Tracheostomy

There is little agreement on the indications, best technique or optimal timing of tracheostomy in ICU patients. Suggested indications for tracheostomy include [22] :

- bypass of glottic and supraglottic obstruction
- access to tracheal toilet
- provision of a more comfortable airway for prolonged ventilatory support
- protection of the airways from aspiration.

In uncomplicated patients, percutaneous tracheostomy performed by an intensivist at the bedside is at least as safe as surgical tracheostomy performed in the operating room and is probably associated with a lower incidence of infectious complications. [23,24] Convenience and cost savings have made percutaneous tracheostomy the procedure of choice in many institutions since Ciaglia's percutaneous technique was first described in 1985. [25] The procedure requires at least two operators, one to perform the surgical procedure and one to provide anaesthesia/analgesia and monitoring of the procedure with fiberoptic bronchoscopy. Prior to skin incision, the use of ultrasound may identify large vessels beneath the skin. After making an adequate skin incision and using blunt dissection with forceps, the existing endotracheal tube is first withdrawn so that its cuff lies just above the vocal cords. The operator confirms the tube position to be above the stoma site by palpation of the trachea. A J-wire is placed in the trachea through a needle inserted through the membrane above or below the second tracheal ring.

Curved dilators can be used to enlarge the stoma. A tracheostomy tube is then inserted into the trachea and the endotracheal tube is removed. A modified tapered dilator (Blue Rhino, Cook Medical; Portex ULTR Aperc) avoids the use of multiple dilators, and is quicker to use, but may cause more tracheal wall injuries and ring fractures. The Griggs technique utilises Kelly forceps, modified to allow it to be guided by the J-wire, to dilate the tract before insertion of the tracheostomy tube. [26] The speed and safety of the two techniques are similar, although the Griggs technique may cause marginally more bleeding and cannula insertion may be more difficult. [27] Fibreoptic bronchoscopy during percutaneous tracheostomy may help to prevent incorrect guidewire placement and tracheal ring rupture or herniation. [28] Complications of tracheostomy are listed in Box 44.2 . Common tracheostomy tube choices include standard cuffed tubes that are used for conventional ventilation, cuffless tubes that are used for patients with tracheal injury or who are ready for decannulation so as to facilitate swallowing and speaking, and fenestrated tubes (cuffed or cuffless) that facilitate coughing and speaking. Extended-length tracheostomy tubes may be required to bypass tracheomalacia or for patients with thick neck tissue. A 7–7.5 mm inner diameter tube is generally suitable for adult females, and 8–8.5 mm for adult males.

Box 44.2

Complications of tracheostomy

Immediate

- Procedural complications
  - Haemorrhage

    - Surgical emphysema, pneumothorax, air embolism
    - Cricoid cartilage damage
- Misplacement in pretracheal tissues or right main bronchus
- Compression of tube lumen by cuff herniation
- Occlusion of the tip against the carina or tracheal wall

Delayed

- Blockage with secretions
- Infection of the tracheostomy site, tracheobronchial tree, and larynx
- Pressure on tracheal wall from the tracheostomy tube or cuff
    - Mucosal ulceration and perforation
    - Deep erosion into the innominate artery
    - Tracheo-oesophageal fistula

Late

- Granulomata of the trachea
- Tracheal and laryngeal stenosis
- Persistent sinus at tracheostomy site
- Tracheomalacia and tracheal dilatation

Awake Intubation Under Local Anaesthesia

Instrumentation of the upper airway in awake patients requires good local anaesthesia to increase comfort, improve cooperation, attenuate cardiovascular responses and reduce the risk of laryngospasm. Rapid transcricoid injection, ‘spray-as-you-go’ with a fibreoptic bronchoscope or nebulised lidocaine to the nares, posterior pharynx and tongue are effective (Table 44.3).[29] Nerve block techniques may improve analgesia but are not essential. Systemic absorption of topically applied lidocaine (maximum dose 4 mg/kg) is variable, and the clinician should be alert for signs and symptoms of toxicity.

Table 44.3

The Difficult Airway

The difficult airway has been described as one in which a conventionally trained anaesthesiologist experiences difficulty with mask ventilation, tracheal intubation or both. Difficult intubations may be expected in 1%–3% of patients presenting for general anaesthesia, and the incidence is likely to be considerably higher in ICU patients.

More than 85% of difficult intubations can be managed successfully by experienced clinicians without resorting to a surgical solution. The experience of the operator is probably the most important factor determining success or failure. Experience implies greater manual skills, better anticipation of problems, use of preprepared strategies, and familiarity with multiple techniques. Thus the training of intensivists must specifically include a variety of airway management strategies and skills.

Assistance and Environment

The patient's condition may rapidly deteriorate as a consequence of a poorly managed airway emergency. The most senior help available should be immediately summoned. If the situation allows, the patient should be moved to the best location for emergency airway interventions, usually, the operating theatre or ICU, and difficult airway equipment requested (see Box 44.1). A skilled intensivist or ear, nose and throat surgeon (gowned and standing by) can help to provide a surgical airway or perform rigid bronchoscopy to remove foreign bodies.

Anticipating and Grading a Difficult Airway

Intubation difficulty can be anticipated or predicted by the presence of the following factors and classifications, [31-33] although the sensitivity and specificity of individual features and classifications tend to be low, when a greater number of positive factors are present, increased predictive accuracy is likely. [33] (see Table 44.4).

Table 44.4

Predictive features of a difficult airway

Anatomical or pathological features of difficult intubation in subjects who otherwise appear normal:	Short neck, especially if obese or muscular (a thyromental distance <6 cm)
	Reduced neck movements, or mouth opening (<3 cm) (e.g. as a result of trismus, osteoarthritis, ankylosing spondylitis and rheumatoid arthritis or perioral scarring)
	Protruding teeth, small mouth, long high curved palate or receding lower jaw
	Space-occupying lesions of the oropharynx and larynx
	Congenital conditions are associated with a higher incidence of difficult intubation (e.g. Marfan syndrome) and obstructive sleep aponea syndrome
	Situational urgency, such as coma or severe hypoxaemia ($SaO_2 < 80\%$)
Mallampati classification[30] of visualising the oropharyngeal structures (a cooperative sitting patient is required for this	Class 1: Visible soft palate, uvula, fauces and pillars
	Class 2: Visible soft palate, uvula and fauces

assessment, and class >2 predicts possible difficulty):	Class 3: Visible soft palate and base of the uvula
	Class 4: Soft palate is not visible
The degree of difficulty experienced visualising the larynx by direct laryngoscopy should be recorded for future reference and is commonly graded by the classification of Cormack and Lehane, and modified by Yentis [31, 32]:	Grade I: Complete glottis is visible
	Grade IIa: partial view of glottis. Grade IIb: only the posterior part of the cords/arytenoids are visible
	Grade III: Epiglottis but not glottis is visible
	Grade IV: Epiglottis is not visible

Failed Intubation and Ventilation Algorithms

A preformulated plan in the event of failed intubation and/or ventilation is essential and a number have been described. The algorithm shown in Fig. 44.1 is an example that can be used to formulate an initial intubation plan, with considered backup options. Effective implementation depends on the appropriate use of the algorithm and airway techniques described above. A number of societal guidelines are available for additional guidance.[7, 34]

Upper Airway Obstruction

Anatomy and Pathophysiology

The upper airway begins at the nose and mouth and ends at the carina. Obstruction is likely to occur at sites of anatomical narrowing, such as the hypopharynx at the base of the tongue, and the false and true vocal cords at the laryngeal opening. Sites of airway obstruction are classified as supraglottic (above the true cords), glottic (involving the true vocal cords) or infraglottic (below the true cords and above the carina).

The upper airway can also be divided into intrathoracic and extrathoracic portions, which behave differently during inspiration and expiration. The intrathoracic airway dilates during inspiration because it is ‘pulled outwards’ by negative intrapleural pressure. Positive intrapleural pressure during expiration causes compression and narrowing. Conversely, the compliant extrathoracic airway, unexposed to intrapleural pressure, collapses during inspiration and expands during expiration. Recalling this phenomenon helps the understanding of typical clinical signs, imaging and flow-volume loops.

Aetiology

Acute upper airway obstruction may result from functional or mechanical causes (Box 44.3). Functional causes include central nervous system and neuromuscular dysfunction. Mechanical causes may occur within the lumen, in the wall or extrinsic to the airway.

Box 44.3

Clinical conditions associated with acute upper airway obstruction

Functional causes

- Central nervous system depression
  - Head injury, cerebrovascular accident, cardiorespiratory arrest, shock, hypoxia, drug overdose, metabolic encephalopathies
- Peripheral nervous system and neuromuscular abnormalities
  - Recurrent laryngeal nerve palsy (postoperative, inflammatory or tumour infiltration), obstructive sleep apnoea, laryngospasm, myasthenia gravis, Guillain–Barré polyneuritis, hypocalcaemic vocal cord spasm

Mechanical causes

- Foreign-body aspiration
    - Infections
    - Epiglottitis, retropharyngeal cellulitis or abscess, Ludwig angina, diphtheria and tetanus, bacterial tracheitis, laryngotracheobronchitis
- Laryngeal oedema
    - Allergic laryngeal oedema, angiotensin-converting enzyme inhibitor associated, hereditary angioedema, acquired C1 esterase deficiency
- Haemorrhage and haematoma
    - Postoperative, anticoagulation therapy, inherited or acquired coagulation factor deficiency
- Trauma
- Burns
    - Inhalational thermal injury, ingestion of toxic chemical and caustic agents
- Neoplasm
    - Pharyngeal, laryngeal and tracheobronchial carcinoma, vocal cord polyposis
- Congenital
    - Vascular rings, laryngeal webs, laryngocele
- Miscellaneous
    - Cricoarytenoid arthritis, achalasia of the oesophagus, hysterical stridor, myxoedema

Clinical Presentation

The signs of sudden complete upper airway obstruction are characteristic and progress rapidly. The victim cannot breathe, speak or cough, and may hold the throat between the thumb and index finger – the universal choking sign. [35] Agitation, panic and vigorous breathing efforts are rapidly followed by cyanosis. Respiratory efforts diminish as consciousness is lost, and death results within 2–5 minutes if obstruction is not relieved. Lethargy, diminishing respiratory efforts and loss of consciousness are late signs of hypoxaemia and hypercarbia. Bradycardia and hypotension herald impending cardiac arrest.

Signs of partial airway obstruction include voice changes and coughing, progressing to drooling, gagging, choking, noisy respiration and inspiratory stridor. Paradoxical chest wall movements and intercostal and supraclavicular retractions may be marked in severe obstruction. Powerful respiratory efforts may produce dermal ecchymoses and subcutaneous emphysema. Respiratory decompensation may be of rapid onset, and progress to complete obstruction.

Special Evaluation or Investigations

If the patient remains stable, specific diagnostic evaluation may be undertaken, provided advanced airway management facilities and skilled personnel are immediately available.

Laryngoscopy and Bronchoscopy

Indirect laryngoscopy in a stable, cooperative patient is useful for diagnosing foreign bodies, retropharyngeal or laryngeal masses and other glottic pathology.

Assessment with a flexible fibreoptic bronchoscope or laryngoscope is the evaluation method of choice in ICU patients and enables direct visualisation of upper airway anatomy and function. The procedure can be performed without transporting the patient and risking complete obstruction. It can be applied to an awake, spontaneously breathing patient and, with care, should not worsen the obstruction. Definitive airway control by intubation can usually be achieved. Disadvantages are the need for a skilled operator and a cooperative patient and a reduced visual field limits effectiveness if blood and secretions are copious.

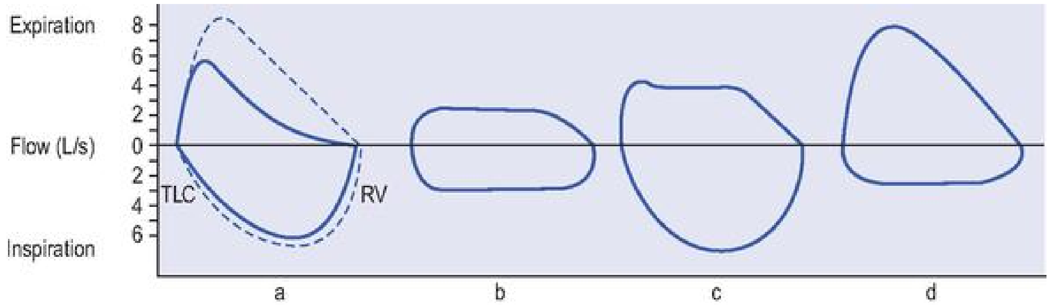
Direct laryngoscopy enables forceps removal of foreign bodies and high-volume suctioning of blood, vomitus and secretions. Endotracheal intubation can rapidly be achieved under direct vision. A disadvantage is the need for general anaesthesia or good local analgesia (often difficult in the emergency setting). Direct laryngoscopy can be traumatic, and may worsen soft-tissue bleeding and oedema.

Radiographic Imaging

Patients with potentially unstable airways should not be transported from a ‘safe’ environment like the emergency room, operating theatre or ICU for radiological investigation until the airway is secure. Anteroposterior and lateral plain neck X-rays may be useful in detecting radiopaque foreign bodies. Computed tomography (CT) scan, preferably with three-dimensional postprocessing, may provide detailed diagnostic information and prognostic at initial evaluation in stable patients, or in those in whom the airway has been secured. [36] Although magnetic resonance imaging (MRI) has been used to image the upper airway, its use in acute airway obstruction is unproven.

Gas Flow Measurement

Flow-volume loop measurement reveals characteristic patterns corresponding to different types and positions of pathological lesions (Fig. 44.3). [37]



The graph with four flow volume loops labelled a to d, each shows flow rate in litres per second against lung volume. Loop a shows a normal curve with a dotted line, which represents predicted values from total lung capacity to residual volume. Loop b shows a scooped-out expiratory curve, which indicates obstructive lung disease. Loop c has reduced lung volumes with a tall, narrow loop, suggesting restrictive lung disease. Loop d shows a flattened inspiratory and expiratory flow pattern, consistent with a fixed upper airway obstruction. The vertical axis represents flow, with expiration above and inspiration below, and the horizontal axis spans from total lung capacity to residual volume.

FIG. 44.3 Flow-volume loops. Patterns resulting from different pathological lesions: (A) lower airway obstruction (e.g. chronic obstructive pulmonary disease or asthma); (B) fixed, non-variable upper airway obstruction (e.g. fibrous ring in trachea); (C) variable upper airway obstruction, intrathoracic (e.g. tumour in the lower trachea); (D) variable upper airway obstruction, extrathoracic (e.g. vocal cord tumour or paralysis). *L/s,* Litres per second; *RV,* residual volume; *TLC,* total lung capacity.

Management

Simplified algorithms to assist the management of partial and complete upper airway obstruction are shown in Figs. 44.4 and 44.5 , respectively. Improvisation may be required for certain difficult problems. The chosen technique should be an appropriate one in which the clinician has reasonable skill and experience. Special techniques in patients with suspected cervical spine instability are discussed in (Chapter 81).

1. Supplemental oxygen (100%) is immediately administered and adequate help is summoned.
2. A choice of equipment for definitive airway control must be available and ready for use (see Box 44.1).
3. In adults IV access should be secured.
4. Initiate continuous monitoring of vital signs and pulse oximetry.
5. The risks and benefits of patient transport before securing the airway must be carefully considered.

Definitive medical and surgical management

The flowchart outlines the assessment and management of incomplete upper airway obstruction. It begins with the upper airway obstruction and branches into stable and deteriorating conditions. For stable cases, oxygen, intravenous access, and pulse oximetry are followed by investigations such as indirect laryngoscopy, neck radiograph, computed tomography scan, magnetic resonance imaging, and flow or volume loop, which lead to diagnosis and definitive medical and surgical management. In deteriorating cases, initial steps include oxygen, intravenous access, pulse oximetry, and continuous medical attendance. This path divides into two timelines. If deterioration occurs within minutes, skilled fiberoptic bronchoscopy and intubation are performed, and if failed, management continues as complete obstruction. If deterioration occurs over minutes to hours, special investigations are performed. Stable cases proceed to diagnosis, while worsening conditions require elective intubation which includes fiberoptic, direct laryngoscopy, retrograde technique, or tracheostomy.

A flowchart titled Complete U A O depicts the management of complete upper airway obstruction. It begins with a central node labelled Complete U A O, which splits into two branches, that is Awake and Unconscious. Under the Awake branch, the next step is Expulsion manoeuvre if F B possible, which leads to a box below labelled Control patient and airway if required: Restraint or sedation or paralysis. Under the Unconscious branch, the next step is Direct laryngoscopy, which leads to Direct laryngoscopy Orotracheal intubation in 15 to 20 seconds. If this fails, the flow moves downward to Surgical airway, e F O N A, Cricothyroidotomy. The path from the Control patient and the airway also connects to the box Direct laryngoscopy, which depicts a unified pathway once airway control is attempted.

FIG. 44.5 Management of complete upper airway obstruction (UAO). Attempts at orotracheal intubation should not take longer than 10–20 seconds. *FB* , Foreign body; eFONA, emergency front of neck access.

Airway Management Techniques in Airway Obstruction

The Unconscious Patient

If the upper airway is obstructed by the tongue and retropharyngeal tissues in an unconscious patient, airway patency is initially achieved by using standard airway manoeuvres [38] and oropharyngeal and nasopharyngeal airways. Definitive airway control should follow if consciousness does not immediately return.

Endotracheal Intubation

1. *Direct laryngoscopic intubation* is the method of choice for the unconscious, apnoeic patient, as it allows rapid evaluation of any supraglottic problem and immediate airway security. *Video laryngoscopy* is an alternative for experienced hands. Both can also be attempted in an awake patient after careful application of local anaesthesia. Although there is some risk of loss of the airway after local anaesthesia, complete loss of the airway under general anaesthesia is common and may be catastrophic.
2. *Awake fibreoptic intubation* in a spontaneously breathing patient is usually safe, but requires a skilled operator. The procedure will take 2–10 minutes or longer, [39] and urgency of the case must be assessed beforehand with this timeframe in mind. Alternatives should be

initiated if the obstruction progresses or if intubation fails after a reasonable time. The following points may assist visualisation in acute upper airway obstruction:

a. The procedure should be clearly explained to the patient.
b. Good local anaesthesia and mucosal vasoconstrictors are important (see Table 44.3).
c. If desired, the suction port of the fibrescope can be used to insufflate 100% oxygen or apply local anaesthetic. This also clears the fibrescope tip of secretions. Additional large-bore suction catheters may help. Failure is most commonly due to excessive secretions and bleeding.

Emergency Front of Neck Access (eFONA)

A surgical airway is indicated when endotracheal intubation is not possible, or when an unstable cervical spine is threatened by available airway techniques. In addition to the cricothyroidotomy techniques described above, emergency surgical tracheostomy under local anaesthesia may be reasonable under some controlled conditions (see Fig. 44.4).

Common Clinical Conditions and Their Management

Foreign-Body Obstruction

Foreign-body obstruction is the most common cause of acute airway obstruction. The elderly, especially those in institutions, are at risk. The use of dentures, alcohol and depressant drugs increases risk. Fatal food asphyxiation or ‘café coronary’ should be considered in any acute respiratory arrest where the victim cannot be ventilated.[40]

Those still able to cough or speak clearly should be given the opportunity to expel the foreign body spontaneously. If not able, expulsion of the foreign body can be attempted with up to five back blows, followed by the Heimlich manoeuvre.[35,38] Unwanted effects, such as vomiting, aspiration, fractured ribs, barotrauma and ruptured organs, have been reported. If these manoeuvres fail, management immediately proceeds as shown in Figs. 44.4 and 44.5 .

Extrinsic Airway Compression

Extrinsic space-occupying lesions can cause upper airway obstruction. Compression from haematomas may be associated with trauma, neck surgery, central venous catheterisation, anticoagulants and congenital or acquired coagulopathies. Haematomas following surgery should immediately be evacuated by removing skin and tissue sutures. If this fails, an artificial airway must be secured immediately. In patients with coagulation abnormalities, intubation is preferred over a surgical airway. Most haematomas secondary to coagulopathy do not require surgical intervention and resolve with conservative therapy (i.e. vitamin K and blood component therapy).

Partial airway obstruction caused by retropharyngeal abscess is best managed by drainage under local anaesthesia. Gentle fibreoptic examination and intubation or direct laryngoscopy and intubation may be considered. Risks are related to inadvertent rupture of the abscess, with subsequent flooding of the airway. Ludwig's angina is a mixed infection of the floor of the mouth resulting in an inflammatory mass in the space between the tongue and the muscles and anterior neck fascia. The supraglottic airway is compressed and becomes narrowed. [41] Direct laryngoscopy is difficult, as the tongue cannot be anteriorly displaced. Awake fibreoptic-guided intubation and a surgical airway, along with antibiotic therapy, are management options.

Intrinsic Airway Compression

Burn Inhalation and Ingestion Injury

Patients with large burn areas (more than 40%), or with severe facial burns or inhalation injury (soot in the nostrils, burns of the tongue and pharynx, stridor or hoarseness) are at risk of developing progressive supraglottic oedema, usually within 24–48 hours. Such patients may require early prophylactic tracheal intubation. Assessment of injury and need for tracheal intubation can best be decided by frequently repeated awake fibreoptic laryngoscopy, together with close clinical observation.[42] Ingestion of hot fluids or corrosive agents can also cause delayed oedema and airway swelling and should be managed similarly.[43]

Adult Epiglottitis

Epiglottitis is an uncommon but increasingly recognised infectious disease in adults.[44] It involves the epiglottis and supraglottic larynx, causing swelling with consequent airway obstruction. *Haemophilus influenzae* and *H. parainfluenzae* , *Streptococcus pneumoniae* , haemolytic streptococci and *Staphylococcus aureus* are common causative organisms. Clinical features are sudden onset of sore throat (pain often greater than suggested by clinical findings), muffled voice, dysphagia, stridor, dyspnoea and respiratory distress. Systemic toxaemia is common. Gentle indirect laryngoscopy, fibreoptic laryngoscopy or lateral neck X-ray confirms the diagnosis. Reported mortality in adults ranges from 0% to 7%.[45]

Airway management is controversial.[45], [46] Some experts recommend securing a definitive airway on presentation, whereas others suggest close observation in the ICU. There are, however, reports of sudden obstruction and death with the latter approach.[46] Onset of dyspnoea, dysphonia, stridor, a rapid clinical course and diabetes may predict the need for intubation.[47] Tracheal intubation and tracheostomy are acceptable, but tracheal intubation may result in better long-term outcomes.

Prior to securing the airway, patient positioning is important, and changing from a sitting to supine position may induce complete obstruction. In more stable patients, awake fibreoptic intubation is preferable if a skilled operator is available. Endotracheal intubation under general anaesthesia following gaseous induction is often recommended. Obstruction can occur, even when this procedure is undertaken by a skilled anaesthetist in the operating room.[46] A skilled assistant, scrubbed and ready to secure a surgical airway, may prevent disaster. Rapid-sequence induction using muscle relaxants is dangerous and should be avoided. Tracheostomy under local anaesthesia is a safe alternative.

Airway management is followed by antibiotics and supportive care. Ceftriaxone 2 g IV daily *plus* clindamycin 600–900 mg 8-hourly, or vancomycin 20–25 mg/kg loading dose followed by 15 to 20 mg/kg 8–12 hourly adjusted according to therapeutic drug monitoring concentrations, are reasonable empirical regimens. Patient factors, especially the presence of significant immunocompromise, local bacterial sensitivities and cultures of blood and epiglottal swabs may influence the antibiotic choice. [48] Supportive care includes adequate sedation and tracheobronchial toilet. Abscesses should be surgically drained. There is no good evidence supporting the use of steroids.

Angioedema

Allergic responses involving the upper airway may be localised or part of a systemic anaphylactic reaction. Angioedema is characterised by subepithelial swelling. Angioedema of the lips, supraglottis, glottis and infraglottis may result in airway obstruction. The systemic reaction consists of variable combinations of urticaria, bronchospasm, shock, cardiovascular collapse and abdominal pain. The aetiology in such presentations is generally mast-cell mediated. Common causative agents are Hymenoptera stings, shellfish ingestion and drugs, especially aspirin and non-steroidal anti-inflammatory agents.

Treatment consists of immediately ensuring an adequate airway (see Figs. 44.4 and 44.5), and administration of oxygen, epinephrine (adrenaline), histamine antagonists and steroids. Close observation in case of relapse for at least 24 hours after severe reactions is necessary. As it is likely to recur, the patient should be followed up and fully investigated.

Hereditary angioedema is a rare, inherited disorder of the complement system, usually caused by functionless or low levels of C1 esterase inhibitor, [49] although other rare forms of hereditary angioedema with normal inhibitor levels and function have been described. Non-pruritic, usually non-painful angioedema involving skin and subcutaneous tissue occurs in various locations, including the upper airway. [50] Precipitating causes include stress, physical exertion and localised trauma (including dental or maxillofacial surgery and laryngoscopy). Acute attacks do not respond to epinephrine, antihistamines or corticosteroids. Management consists of establishing a secure airway and infusion of C1 esterase inhibitor concentrate, such as purified C1-INH, CSL Behring (20 U/kg) which has an onset of action of 30–60 minutes. [50, 51] If not available, fresh frozen plasma (2 units, repeated every 2–4 hours until clinical improvement) may be considered, with care taken to manage patient fluid status.

Icatibant acetate, a subcutaneous synthetic peptide blocker of the bradykinin-2 receptor, and ecallantide, a subcutaneous recombinant protein kallikrein antagonist, have both recently become available for the symptomatic treatment of hereditary angioedema. [52] Guidelines recommend the use of C1-inhibitor concentrate for preoperative prophylaxis, but if not available, danazol 400–600 mg/day can be used for 5 days before and 2–3 days after the procedure.

Angiotensin-converting enzyme inhibitor-related angioedema is increasingly seen. It usually develops more slowly (over 24 h or more), is not associated with other signs of allergy, and is the result of reduced bradykinin metabolism. [53] Treatment focuses on airway support, with resolution expected in 3–6 days after removal of the offending agent.

Postextubation Laryngeal Oedema

Laryngeal oedema following extubation occurs in about 20% of adults but is severe enough to precipitate reintubation in only 1%–5%. The risk of postextubation oedema may be increased by excessive airway manipulation, traumatic intubation, high cuff pressures and duration of tracheal intubation greater than 36 hours; however, after 1 week the risk appears to decline again. Prophylactic use of corticosteroids (e.g. methylprednisolone initiated 12 hours before planned extubation at 20 mg IV 4-hourly with the last dose immediately prior to tube removal) has been shown to reduce the incidence of postextubation laryngeal oedema and subsequent reintubation. [54] Treatment in adults is conservative, with close observation and humidified oxygen therapy. Nebulised plain epinephrine (1–2 mL 1:1000 solution diluted with 2 mL saline or undiluted 1:1000 solution 4–5 mL) or racemic epinephrine (0.25–0.5 mL 2.25% solution in 2–4 mL saline) have been used. Nebulisation may need to be repeated every 30–60 minutes.

Postobstruction Pulmonary Oedema

Postobstruction pulmonary oedema, also known as negative-pressure pulmonary oedema, may occur after general anaesthesia (incidence 0.05%–

0.1%) or after relief of acute upper airway obstruction (incidence 11%).[55] This appears to be related to the markedly decreased intrathoracic pressure caused by forced inspiration against a closed upper airway, resulting in transudation of fluid from pulmonary capillaries to the interstitium. In addition, increased venous return may increase pulmonary blood flow and pressure, further worsening oedema. Hypoxaemia, the hyperadrenergic stress state and increased ventricular afterload may also affect capillary hydrostatic pressure, although pulmonary capillary occlusion pressure is often normal. The oedema usually occurs within minutes after the relief of the obstruction but may be delayed several hours.[56] Management includes the application of continuous positive-airway pressure or positive-pressure ventilation with PEEP, maintenance of airway patency, oxygen therapy, diuretics, morphine and fluid restriction.

Pulmonary embolism

Aimee Brame and Brijesh Vipinchandra Patel

Introduction

Pulmonary embolism (PE) is a common presenting pathology in acute care.

It may present classically, with dyspnoea and chest pain but often the symptoms are more indolent, and clinicians require a high index of suspicion to make the correct diagnosis.

Around 10% of deaths in hospitals are due to pulmonary emboli and up to two-thirds are missed. [1]

It is important to have an adequate understanding of the pathophysiology as well as a rapid and reliable strategy for investigation and management. This is particularly important in intensive care unit (ICU) patients where diagnosis can be difficult, and PE may be life threatening. While admission rates for PE are rising, outcomes are improving overall. [2] However, mortality amongst haemodynamically unstable patients remains high. [2]

Early deaths in PE are usually the result of acute right ventricular (RV) failure and cardiogenic shock. After the first few days, mortality is less common and mostly determined by recurrent thromboembolic events and the underlying disease state.

Aetiology

Deep venous thrombosis (DVT) and PE are components of a single disease termed venous thromboembolism (VTE). Embolisation of DVT to the pulmonary arteries leads to PE. The incidence of VTE in the population is about 1–2 in 1000 per year and is more common both with advancing age and in males.[1]

Predisposing risk factors for VTE involve one or more components of the Virchow triad: (1) venous stasis, (2) vein wall injury and (3) hypercoagulability of blood. In addition to the main factors such as immobility (from any cause), surgery, trauma, malignancy, pregnancy, thrombophilia and autoimmune disorders have also been associated with increased risk of PE (see Box 45.1).[2,3]

Box 45.1

Risk factors for venous thromboembolism

Primary hypercoagulable states (thrombophilia)

- Antithrombin III deficiency
- Protein C deficiency
- Protein S deficiency
- Resistance to activated protein C (inherited factor V Leiden mutation)
- Hyperhomocysteinaemia
- Lupus anticoagulant (antiphospholipid antibody)

Secondary hypercoagulable states

- Immobility
- Surgery
- Trauma
- Malignancy
- Pregnancy and puerperium
- Obesity
- Smoking
- Oestrogen-containing oral contraception or hormone replacement therapy
- Indwelling catheters in great veins and the right heart
- Burns

Patients with limb paralysis (e.g. spinal injuries)
Heart failure
Increasing age
Autoimmune and chronic inflammatory diseases such as inflammatory bowel disease
COVID-19

Most PE results from DVT in the lower limbs, pelvic veins or inferior vena cava (IVC), although thrombi can develop in the right atrium, right ventricle and upper limbs. Up to 40% of patients with DVT develop PE, although if the DVT is isolated to below the knee, then clinically obvious PE is rare. [4]

COVID-19 resulted in a significant increase in the incidence of venous thromboembolism as well as in-situ thrombosis, especially in patients requiring mechanical ventilation. A small UK study showed DVT and PE rates of 59% and 43% respectively, of note 49% of the PEs were centrally located. [5] The profound inflammatory response to COVID-19 causes an acute-phase response and endotheliitis which results in both a coagulopathy and prothrombotic picture, with micro and macro thrombosis in lungs and other organs and vessels. [6]

Pathophysiology

The effects of PE depend on the clot burden, location and underlying cardiopulmonary disease. They can range from incidental and clinically irrelevant to significant with severe obstruction to the pulmonary circulation and sudden death. Haemodynamic decompensation not only results from physical obstruction to blood flow but also hypoxic pulmonary vasoconstriction and the release of vasoactive substances (such as serotonin, histamine and thromboxane A_2 from platelets) causing elevated pulmonary vascular resistance and acute pulmonary hypertension. [7]

Acute pulmonary hypertension increases RV afterload and RV wall tension which leads to RV dilatation and impaired coronary perfusion in diastole. [6] Pulmonary emboli can result in obstructive shock, with RV systolic failure, paradoxical interventricular septal shift and pericardial constraint leading to impaired LV filling, reduced coronary perfusion, ischaemia and left ventricular (LV) dysfunction. In patients with underlying cardiorespiratory disease, a small PE can have profound consequences.

Pulmonary arterial obstruction causes a mismatch between lung ventilation and perfusion. Diversion of blood away from areas of clot to other areas increases perfusion to these areas but does not increase ventilation, resulting in hypoxaemia.[8] The ventilation of lung units that have reduced or no perfusion also causes increased dead-space ventilation and an increase in the end-tidal to arterial CO_2 gradient. Alveolar hyperventilation also occurs leading to hypocapnia. Increased right atrial pressure can open a patent foramen ovale, which may result in right-to-left intracardiac shunting, manifesting as either refractory hypoxaemia or paradoxical (arterial) embolisation commonly to the brain leading to cerebral infarction.

Finally, a reduced cardiac output results in increased O_2 extraction and lower pO_2 in returning blood, this then amplifies the hypoxaemia, particularly in those with underlying lung disease.[7]

Clinical Presentation

Thrombotic events are common in critically unwell patients both before and after ICU admission. The prevalence of venous thromboembolism in the 3 months prior to ICU admission is around 3.6%. Despite VTE prophylaxis, a further 4% will develop VTE during their admission. Critical care risk factors include central venous catheters, sepsis, renal replacement therapy, respiratory failure and previous clots.[9]

The diagnosis is frequently overlooked or is difficult to confirm because several more prevalent cardiopulmonary diseases, including heart failure, pneumonia and chronic lung diseases, have similar clinical features. Up to one in six patients have the diagnosis made more than 10 days after symptom onset.[10]

Clinical assessment should raise the suspicion of PE but is neither sensitive nor specific enough to reliably confirm or exclude the diagnosis on its own. Clinical decision rules (CDRs) for PE (Geneva, Pisa, Charlotte, Pulmonary Embolism Rule-out Criteria [PERC] and Wells scores) have been widely validated in outpatients but their performance in hospitalised patients is not clear. [11] None of these CDRs are reliable predictors of pulmonary embolism in critical care.

Patients can have their probability assessed as unlikely based on history and clinical risk (in whom PE can be safely ruled out with a negative d-dimer result) or likely (in whom an imaging test is required and in whom prompt anticoagulant therapy should be considered). The differential diagnoses are listed in Box 45.2 .

Box 45.2

Differential diagnosis of pulmonary embolism

Acute myocardial infarction
Acute coronary syndrome
Acute pulmonary oedema
Pneumonia
Asthma or exacerbation of chronic obstructive pulmonary disease
Pericardial tamponade
Pleural effusion
Fat or amniotic fluid embolism
Pneumothorax
Aortic dissection
Rib fracture
Musculoskeletal pain
Anxiety

Symptoms

Dyspnoea, pleuritic chest pain and haemoptysis are the classic symptoms of PE. Many patients will have at least one of these symptoms, with dyspnoea being the most common. The combination of pleuritic chest pain and haemoptysis reflects a late presentation where pulmonary infarction has occurred. If syncope occurs, and there is no other obvious cause, this can indicate a high-risk PE even in the absence of haemodynamic compromise.

Physical Signs

Physical signs can be absent, but the most frequent sign is tachypnoea. Others include cough, tachycardia, fever and signs of RV dysfunction (raised jugular venous pressure, parasternal heave and loud pulmonary component of the second heart sound). In high-risk PE, signs may include hypotension, pale mottled skin and peripheral or even central cyanosis. A central PE may produce typical angina symptoms due to RV ischaemia. [12]

It is important to examine for signs of DVT particularly in the legs.

Investigations

The diagnosis of PE requires a high level of clinical suspicion and the appropriate use of investigations. The optimal investigation strategy depends upon the individual patient and institution; however, multidetector CTPA scanning is now the imaging test of first choice in a patient without haemodynamic instability. A transthoracic echocardiogram may be a more appropriate first-line investigation in a patient who is unstable. [13] A suggested investigation algorithm is shown in Fig. 45.1 .

The flowchart for suspected pulmonary embolism begins with assessing hemodynamic instability. If unstable, transthoracic echocardiography is performed. If right ventricular dysfunction is present, and computed tomography pulmonary angiography is feasible, C T P A is done. A positive result leads to treatment of high-risk pulmonary embolism; a negative result prompts a search for other causes of shock. If C T P A is not feasible, treatment is started based on high clinical suspicion. If the patient is stable, clinical probability is assessed. A low probability leads to D-dimer testing; if negative, other causes are investigated. A high D-dimer or high probability leads to C T P A. A positive C T P A confirms pulmonary embolism; a negative C T P A rules it out.

FIG. 45.1 Diagnostic algorithm for critically unwell patients with suspected pulmonary embolism presenting with and without haemodynamic instability. (Modified from Konstantinides SV, Meyer G, Becattini C, et al. 2019 ESC Guidelines for the diagnosis and management of acute pulmonary embolism developed in collaboration with the European Respiratory Society (ERS): The Task Force for the diagnosis and management of acute pulmonary embolism of the European Society of Cardiology (ESC). *Eur Respir J* . 2019;54(3):1901647; doi:10.1183/13993003.01647-2019.)

D-Dimer

The serum D-dimer level, which becomes elevated when acute thrombus formation occurs, is useful for exclusion of VTE, particularly when it is normal and combined with a low-risk clinical assessment.[14] Because of the sensitivity of the tests, particularly using enzyme-linked immunosorbent assays (ELISA), enzyme-linked immunofluorescence assays (ELFAs) and latex quantitative assays, negative D-dimer tests are highly predictive of the absence of both DVT and PE.

A high D-dimer concentration is also an independent predictive factor associated with mortality.[15, 16] Unfortunately, D-dimer levels are often elevated in ICU patients for reasons including infection, inflammation, cancer, surgery and trauma, acute coronary syndrome, stroke, peripheral artery disease or ruptured aneurysm, those who have prolonged symptoms and who are already receiving therapeutic anticoagulant therapy. Age-adjusted D-dimer limits should be used in older adults as the upper limit of normal increases with age [13, 17]). In addition, reporting units and performance of the assay used by the laboratory need to be considered when using D-dimer cut-offs to rule out PE.[17]

Biomarkers

Although of little use for confirming or excluding the diagnosis, biomarkers can assist in risk stratification of patients with diagnosed PE.[18] Levels below the cut-off for established biomarkers such as troponin, B-type natriuretic peptide (BNP) and N-terminal pro-BNP (NT-pro-BNP) can help stratify patients into a low-risk category. Admission troponin levels may be falsely low in some patients who present early, so the troponin level at 8 hours is a better marker for risk stratification for these patients.[19] Heart fatty acid binding protein (H-FABP) is a cytoplasmic protein which appears in the circulation as early as 90 minutes after myocardial injury and is an emerging biomarker for predicting adverse outcomes after PE.[20] These biomarkers should be used in conjunction with other tests investigating the presence of RV dysfunction (echocardiography or CTPA) to stratify these patients, as none of these biomarkers alone can separate patients with low risk from those with higher risk of death or PE-related complications with an acceptable degree of certainty.[21]

Arterial Blood Gases

A normal arterial blood gas profile does not exclude the diagnosis of PE; however, hypoxaemia (with a widened alveolar-arterial oxygen gradient), hypocapnia and an increased end-tidal CO_2 gradient should raise the suspicion of PE, even if these are common findings in critically ill patients for other reasons. Metabolic acidosis may be present if shock from a large PE occurs. Capnography may evolve into a useful tool to rule out PE in patients with positive d-dimer tests but at present, the method and optimal cut-offs are unclear.[22]

Electrocardiograph

A normal electrocardiograph (ECG) is found in about one-third of patients. Apart from sinus tachycardia (which is non-specific), the most frequent ECG abnormalities are non-specific S–T depression and T-wave inversion in leads V1–V4, right bundle branch block, S1Q3T3 pattern (deep S-wave in lead I and a Q-wave and inverted T-wave in lead III) and S-T segment elevation in lead AVR, reflecting right heart strain. These ECG abnormalities and the presence of atrial fibrillation are associated with a higher risk of adverse outcomes.[23] The ECG is also useful in excluding acute myocardial infarction and pericarditis. The presence of T-wave inversion in both lead III and V1 increases the likelihood of PE as compared to acute coronary syndrome.[24]

Chest X-Ray

The chest X-ray is neither sensitive nor specific for pulmonary embolism. It is often normal or only slightly abnormal with non-specific signs such as cardiac enlargement, pleural effusion (in 35%), elevated hemidiaphragm, atelectasis and localised infiltrates. More specific findings, including focal oligaemia (Westermark sign, 10%), a peripheral wedge-shaped density above the diaphragm (Hampton hump, 20%), an enlarged (1) main pulmonary artery (Fleischner sign 20%), (2) right descending pulmonary artery (Palla sign) or (3) right pulmonary artery with sudden cut- off (Chang sign), are uncommon and may be difficult for non-radiologists to identify.[25], [26] The chest X-ray is useful in identifying an alternative diagnosis such as pneumothorax, pneumonia, acute pulmonary oedema, rib fracture and pleural effusion.

Confirmatory Imaging Tests Including CTPA Scan

Imaging is required in any patient with a high or likely clinical probability. As the technology has improved, CTPA scanning, especially the multidetector scanner (MD-CTPA),[27] has now largely replaced lung ventilation-perfusion (V/Q) scanning as the cost-effective and clinically reliable imaging procedure of choice in patients with suspected PE.[28] This is because the CTPA scan has the advantages of greater diagnostic accuracy, ready availability at most hospitals, more rapid image acquisition time and the possibility of making an alternative diagnosis. High-resolution images to the level of segmental and in some cases subsegmental pulmonary arteries can be obtained in a short time period (often a single breath-hold). When compared with conventional angiography it appears reliable, with excellent sensitivity, specificity and accuracy.[29] It is therefore recommended that the CTPA scan should be the principal imaging test for patients with high and moderate probability of PE.

Although inconclusive CTPA scans occur in around 10%, a negative CTPA result means that withholding anticoagulant therapy is safe.[30] An emerging problem of CTPA scanning, however, is the increased detection (around 10%) of small peripheral emboli in subsegmental pulmonary arteries due to increased visualisation of these arteries. The clinical significance of these findings in critically ill patients is unknown; however, these are usually unlikely to lead to a poor outcome if left untreated, unless the patient has co-existing DVT, cancer or is symptomatic.

The CTPA scan can also be used to assess the severity of PE. An increased RV/LV ratio, high thrombus load and central location of the clot are associated with worse clinical outcomes. Increased RV/LV ratio is the most significant marker of severity of PE.[31] Severity stratification is further increased by combining CTPA scanning with other tests such as troponin, BNP or NT-Pro-BNP.[18] CTPA scanning may also identify the causative DVT in the veins of the legs, pelvis and abdomen or detect alternative or additional diagnoses such as a pulmonary mass, pneumonia, emphysema, pneumothorax, pleural effusion or mediastinal adenopathy (Fig. 45.2).

Three axial computed tomography scan images of the thorax are labelled Part A, Part B, and Part C. Part A shows a transverse section at the upper thoracic level with the ascending aorta, pulmonary artery, and part of the superior vena cava visible, along with both lungs showing normal aeration. Part B is a mid-thoracic section displaying the heart, pulmonary vessels, and well-aerated lungs. Part C is a lower thoracic slice that shows the left ventricle and surrounding cardiac structures, with both lungs partially visible. All images appear in grayscale with contrast enhancement, which highlights the vascular structures.

FIG. 45.2 Computed tomography (CT) scanning and pulmonary embolism. Three CT images from the same patient demonstrating the ability of CT to detect pulmonary emboli, assess severity and confirm additional diagnoses. (A) (mediastinal window): filling defects in the right pulmonary artery and inferior branch of the left pulmonary artery. A pulmonary artery catheter is also in situ. (B) (lung window): a left pneumothorax with pleural adhesions, and a small area of left-sided posterior consolidation. (C) (mediastinal window): dilatation of the right ventricle relative to the left ventricle.

Despite the increased use of the CTPA scan, the SPECT V / Q scan retains a role when CTPA is either unavailable or contraindicated (e.g. significant renal impairment, anaphylaxis to intravenous contrast or pregnancy). [32] SPECT V / Q has an equivalent diagnostic yield to CTPA, with a lower radiation dose, despite improvements in technology progressively reducing the radiation dose of CTPA. V / Q scanning also allows quantification of regional blood flow within the lungs which may be required in the assessment of chronic thromboembolic pulmonary hypertension.

PE may also be diagnosed by using a combination of real-time magnetic resonance angiography (MRA) and contrast-enhanced MRA, which seems to have the highest diagnostic yield amongst MRI techniques. While lack of radiation and nephrotoxic intravenous contrast are obvious advantages, significant numbers of low-quality images and poor sensitivity for subsegmental PE remain a problem, restricting wider use of this modality.[33]

Echocardiography

Because of its portability, echocardiography is incredibly useful in the assessment of critically ill patients with probable PE. Many patients with PE have an echocardiographic abnormality, the most common being RV dilatation with basal RV/LV ratio >1.0 (present in over 25%[13,34]), features of RV pressure overload (flattened intraventricular septum, distended IVC) and RV dysfunction.

In a shocked patient with a suspected PE, the presence of right heart thrombus, the 60/60 sign, McConnell's sign or early-mid systolic notching can justify emergency reperfusion treatment even in the absence of cross-sectional imaging.[13] The echocardiographic features in acute pulmonary embolism are listed in Box 45.3 .

Box 45.3

Echocardiographic features of pulmonary embolism[13,35,36]

Enlarged Right Ventricle in parasternal long axis

Dilated RV with basal RV/LV ratio >1.0 (sensitivity 92%)

Flattened intraventricular septum

Distended IVC with reduced inspiratory collapse

60/60 sign – Pulmonary valve acceleration time <60 ms in the presence of a tricuspid regurgitation (TR) pressure gradient of <60 mm Hg or TR velocity <3.9 m/s (highly specific)

Early systolic notching of the pulmonary doppler flow (92% of patients with Intermediate-high risk PE) (highly specific)

McConnell sign (regional RV dysfunction, with akinesia of the mid free wall but normal movement at the apex)

Mobile thrombus in right heart or pulmonary arteries.

Features of impaired function-reduced TAPSE and decreased peak systolic velocity of tricuspid valve annulus (<9.5 cm/s)

It must be noted that a negative transthoracic echocardiography does not exclude PE, but the lack of high-risk features reduces the risk of adverse events and can also suggest a differential diagnosis for example, aortic dissection, cardiac ischaemia and pericardial tamponade.

Echocardiography is most valuable in the urgent bedside assessment of shocked patients who are too haemodynamically unstable to tolerate computed tomography (CT imaging).

Diagnosis of Deep Venous Thrombosis Using Ultrasound

Doppler ultrasound has been recommended to search for DVT in the leg veins from where over 90% of emboli originate. If a leg DVT is confirmed, anticoagulation is required unless the DVT is entirely below the knee where the associated morbidity is low. Ultrasound is highly accurate in symptomatic or proximal DVT, although, in asymptomatic patients, ultrasound is much less likely to find DVT, meaning the absence of DVT does not exclude PE. The best use of ultrasound is when a CTPA scan is contraindicated. [36] Proximal compression ultrasound (CUS) with four-point compression (bilateral femoral vein at the saphenofemoral junction and bilateral popliteal veins) has excellent specificity for the diagnosis of PE in the right clinical setting and hence is useful for ruling in the diagnosis in patients in whom CTPA is contraindicated or carries a significant risk of harm (e.g. pregnancy, allergy to intravenous contrast or renal dysfunction). [37]

Investigation Strategy in Haemodynamically Stable Patients

A CTPA scan is the preferred initial test. The presence of clots within pulmonary arteries confirms the diagnosis of PE.

- An echocardiograph should be considered to assess for RV dysfunction and markers of high-risk disease with adverse prognosis:
- Raised troponin (repeated at 8 hours if not elevated on admission), BNP or NT-pro-BNP to aid risk stratification.
- If a CTPA scan is not possible (contraindicated or unavailable), an alternative investigation such as a V / Q scan, MRA or ultrasound should be considered.
- None of these tests excludes PE but a negative result in a haemodynamically stable patient means that the outcome without anticoagulation is unlikely to be poor.

Investigation Strategy in Haemodynamically Unstable Patients

- An echocardiograph (transoesophageal if patient is intubated in the absence of contraindications) should be the first test performed.
- If the patient has acute RV dilatation with systolic dysfunction and visible embolus, PE is confirmed.
- If there is RV dilatation with or without systolic dysfunction but no visible embolus, then a CTPA scan is required depending on how unstable the patient is.
- If there is no RV dilatation, the haemodynamic instability is unlikely to be due to PE (although this cannot be excluded completely). Finding an alternative diagnosis is the priority.
- If echocardiography is not readily available, a CTPA scan should be performed unless a proximal CUS can expediently confirm a DVT. Absence of a DVT on proximal CUS is insufficient to rule out PE.

Management

Management Principles

Once PE has been confirmed, patients at all levels of severity should receive anticoagulation with either unfractionated or low-molecular-weight heparin (LMWH), or direct oral anticoagulants (DOACs), to prevent further embolisation. In more severe cases of PE, however, the key principle is embolus destruction to maximise a more rapid effect on relief of RV dysfunction. To assist in planning the management it is important to grade the severity of PE. Prediction models based on clinical findings at diagnosis may be useful for the prognostic assessment of patients with acute PE. The PE severity index (PESI) is the most extensively validated prognostic clinical score [38] and a simplified version of this has been developed. [39] By convention, patients are classified into high-risk (previously massive), intermediate-risk (previously submassive) and low-risk categories. Low-risk patients may be treated in the outpatient setting, as their 30-day mortality risk is low. Those in intermediate and high-risk groups have the highest 30-day mortality. It is crucial that these patients are identified so that appropriate investigations and reperfusion and other supportive treatments can be commenced without delay. [13]

The place of these indices in critical illness is yet to be determined and it may be that a combination of a predictive scoring system with a combination of imaging for RV dysfunction and cardiac laboratory biomarkers is the most useful. [40]

High-Risk Pulmonary Embolism (Haemodynamically Unstable/Shocked)

Patients with PE and hypotension have a high risk of death despite treatment. If cardiopulmonary resuscitation is required, the risk is even higher. These patients have the most benefit from a strategy that includes attempts at urgent embolus destruction (with thrombolytic therapy or embolectomy), concurrent haemodynamic support and prevention of further embolisation.

Intermediate-Risk Pulmonary Embolism (Haemodynamically Stable With Evidence of Right Ventricular Dysfunction and Myocardial Injury)

Patients with PE and evidence of RV dysfunction have higher mortality (around 15%) and recurrence rates than those with normal RV function. [41] They can also develop shock and RV thrombi more frequently. These patients require prevention of further embolisation but also warrant strong consideration of embolus destruction using thrombolytic therapy. Thrombolytic therapy in these patients has been shown to reduce haemodynamic decompensation and mortality at the cost of increased risk of intracranial haemorrhage and major extracranial bleeding, especially in elderly patients. [40], [42] Consideration should be given to low-dose thrombolysis or catheter-based techniques. [43-46]

Low-Risk Pulmonary Embolism (Haemodynamically Stable With No Right Ventricular Dysfunction)

Patients with PE who have normal blood pressure, normal RV function (determined by echocardiography or CTPA scan) and non-elevated cardiac biomarkers have a low risk of death or recurrence. The predominant management goal is the prevention of further embolisation using anticoagulant therapy, as treatment focused on embolus destruction is unlikely to confer additional benefits.

In summary, the major principles of management are therefore:

- Prevention of further embolisation (for high-risk, intermediate-risk and low-risk PE)
- Embolus destruction (for high-risk and intermediate-risk PE)
- Concurrent haemodynamic support (for high-risk PE).

Prevention of Further Embolisation

Anticoagulant Therapy

Heparin has been known to prevent recurrence and reduce mortality from PE for over 45 years. LMWHs are as effective and safe as unfractionated heparin (UFH) [46] and may even be better. [47] LMWHs offer several advantages over UFH, including a longer half-life, increased bioavailability, a more predictable dose response and fewer requirements for monitoring and dose adjustments. They should be readily used in stable patients with PE.

UFH should be used in patients with renal impairment and following thrombolytic therapy or embolectomy as it can be easily and rapidly reversed. Intravenous UFH should be administered after a bolus and initial monitoring should be with 6-hourly activated partial thromboplastin time (APTT) testing or anti-Xa levels as per unit policy. Since subtherapeutic levels of anticoagulant therapy increase the risk of recurrence, it is important to achieve therapeutic heparinisation rapidly. Weight-based dosing of heparin should be used, as target anticoagulation levels are reached sooner. [48] It is noteworthy that in the context of thrombolysis, UFH infusion should be withheld for 12 hours if twice-daily LMWH was being used prior to thrombolysis; or for 24 hours if using once-daily LMWH. If a patient is on UFH infusion prior to thrombolysis, UFH should be stopped during streptokinase or urokinase infusion but can continue during recombinant tissue plasminogen activator (rtPA) infusion. [13]

The predominant complications of both UFH and LMWHs are bleeding related. These include bleeding peptic ulcer, stroke, retroperitoneal haematoma and postsurgical wound haemorrhage. Heparin-induced thrombotic thrombocytopenia syndrome (HITTS) can also occur. Bleeding complications and HITTS appear to be less common when LMWHs are being used. A number of conditions are considered to be relative contraindications to anticoagulant therapy. These include active peptic ulceration, recent surgery, recent trauma and recent cerebral haemorrhage. In each individual patient the risk-to-benefit ratio (taking into account the severity of the PE) should be considered before anticoagulation is withheld from the patient.

Oral anticoagulants should be started as soon as possible so that LMWH or UFH can eventually be ceased. For warfarin, this is generally when the international normalised ratio is greater than 2.0. Although warfarin (a vitamin K antagonist [VKA]) has been commonly used as the long-standing anticoagulant of choice, adverse events leading to hospitalisation remain common. [49] DOACs, namely factor Xa antagonists (rivaroxaban, apixaban, edoxaban) and direct thrombin inhibitors (dabigatran), are increasingly being used for the treatment of PE. These have the advantage of a more rapid onset of action, predictable anticoagulant effects and no need for routine laboratory monitoring. Both direct thrombin inhibitors and factor Xa antagonists have been shown to be as efficacious as LMWH-VKA combination in patients who are haemodynamically stable and are associated with a lower risk of bleeding. [50] In addition, rivaroxaban and apixaban do not require a heparin lead-in period as opposed to edoxaban and dabigatran, which need at least 5 days of heparin lead-in. While there is no proven advantage of one DOAC over another, pharmacokinetics, severity of disease, individual patient characteristics and preferences should be considered carefully when choosing between these agents. Amongst DOACs, higher severity of disease may favour agents with overlap with heparin while mild to moderate renal impairment may favour factor Xa antagonists over dabigatran. However, severe renal impairment or doubts about compliance favours VKAs, as treatment can be monitored. Recent approval of a reversal agent for dabigatran (idarucizumab) and emerging reversal agents for factor Xa antagonists (andexanet alfa) may help in the management of bleeding complications in patients on DOACs. [50-52]

Inferior Vena Cava Filter

IVC filters are another method used to prevent further embolisation. These can be permanent, temporary (needing removal in a few days) or retrievable (can be left in situ for longer). IVC filters are indicated for patients in whom anticoagulation is contraindicated and those who experience recurrent PE despite adequate anticoagulation. [13] They do not have a role in patients with high or intermediate-risk PE who have undergone open surgical embolectomy or thrombolysis [13] and they do not offer any further benefit if added to therapeutic anticoagulation. [53] Insertion is usually performed percutaneously in a radiology department but it can be done at the bedside. They lower early recurrence rates but increase long-term DVT recurrence rates. [54] Newer retrievable designs may be more efficacious and safer if removed at the appropriate time. If not removed, complications related to these filters may nullify their immediate benefits in the longer term. [55]

Embolus Destruction

Thrombolytic Therapy

Intravenous thrombolytic drugs result in dramatic and immediate haemodynamic improvement in some patients by dissolving the embolus and rapidly reducing pulmonary arterial obstruction, reducing pulmonary artery pressure and pulmonary vascular resistance.[13] The greatest benefit is seen within 48 hours of symptom onset, but thrombolysis is still beneficial for up to 14 days. In shocked patients, thrombolysis results in a significant reduction in the combined outcome of mortality and recurrent PE, but this was associated with a 9.9% severe bleeding rate and 1.7% rate of intracranial haemorrhage.[13]

In normotensive patients with RV dysfunction, thrombolysis reduced the risk of haemodynamic collapse (2.6% vs. 5.6%), compared with IV heparin alone, but was accompanied by an increased risk of haemorrhagic stroke (2.0% vs. 0.2%) and extracranial bleeding (6.3% vs. 1.2%).[56]

It is therefore recommended that once the diagnosis of high-risk PE has been confirmed, thrombolytic therapy should be given without delay unless there is a clear contraindication.[13] Around 90% of patients should respond to thrombolytic therapy. The clinical benefits and relative underuse of this therapy have been recently highlighted using observational data.[57]

For patients with intermediate-risk PE, the benefits of thrombolysis in terms of improvement in haemodynamics and possible lower risk of adverse events like poor functional capacity at 90 days post thrombolysis should be carefully balanced with the increased risk of bleeding.[58,59] Consideration should be given to low-dose thrombolysis or catheter-based techniques.[43-45] The decision to use thrombolysis for patients with intracardiac thrombi needs to be similarly individualised. Even though thrombolysis has been recommended in recent guidelines, propensity score-matched analysis of data from a large PE-specific registry did not support use of reperfusion treatment over anticoagulation with a higher risk of recurrence in the reperfusion treatment arm.[60]

Accelerated IV administration of recombinant tissue-type plasminogen activator (tPA) is preferable to prolonged infusions of first-generation thrombolytic therapies, however, the choice of drug is less important than the choice to give thrombolytic therapy at all. Suggested doses are recommended in Table 45.1 and can be administered through either a peripheral or a central venous catheter. Once the thrombolytic therapy has been administered, heparin should be commenced.

Table 45.1

Recommended doses of thrombolytic drugs for pulmonary embolism

Urokinase	4400 units/kg bolus (over 10 minutes) followed by 4400 units/kg per hour for 12 hours
Streptokinase	250,000 unit bolus (over 15 minutes) followed by 100,000 units/hour for 24 hours
Alteplase	10mg bolus followed by 90mg over 2 hours if ≥65kg. Max dose 1.5mg/kg in patients <65kg
Reteplase	10 unit boluses 30 minutes apart

Major clinically significant bleeding can occur in up to 10% of patients, although cerebral haemorrhage is fortunately uncommon (2%)[56, 61] It is difficult, however, to predict those patients who are at the highest risk for bleeding.

Recent surgery is not an absolute contraindication and patients should have their individualised risks and benefits weighed up; in shocked patients with PE, the balance appears to be in favour of thrombolytic therapy for almost all patients.

If significant bleeding occurs the thrombolytic therapy should be ceased, and fresh frozen plasma and cryoprecipitate can be given to replace coagulation factors.

Catheter-directed Thrombolysis

Catheter-directed thrombolysis (CTD) is an increasingly used treatment option for delivering tPA via a multiside hole catheter placed directly into one or both pulmonary arteries. This results in rapid reduction in right ventricle dimensions and pulmonary artery systolic pressures and is associated with a dramatic reduction in bleeding risk (RR0.61) [61] compared with systemic infusion. [56] A recent metanalysis of over 20k patients across 44 studies showed CDT was associated with significantly lower in-hospital mortality (RR 0.43), intracerebral haemorrhage (OR0.44) and major bleeding (OR0.61) when compared to systemic thrombolysis. When compared to heparin alone, there was a decreased risk of death (OR0.36) with no increase in risk of haemorrhage [56], [61] even in those over 65 years. [62]

Mechanical Thrombectomy

In patients with high-risk pulmonary embolism (PE) who cannot receive thrombolysis, mechanical thrombectomy can be considered. There are a number of devices and methods that can be used; suction catheters, thrombus macerators, rotational thrombectomy (Treretola/Cleaner), rheolytic fragmentation (Angiojet) and catheter thrombectomy(Flowtreiver/Indigo/Angiovac). These devices are safe and effective in reducing mean pulmonary artery pressures and oxygen requirements and have reduced bleeding rates (1%) compared with both anticoagulation and fibrinolysis. [63]

As the safety profile of catheter-based techniques improves they should be considered more commonly in patients with intermediate-risk to high-risk PE who can be safely transferred to the radiology department in centres where requisite expertise is available. [13]

Surgical Embolectomy

The merit of surgical pulmonary embolectomy, which has traditionally been seen as a life-saving option for moribund patients with PE, has been questioned since the advent of reliable thrombolytic therapy. Embolectomy surgery results vary widely and there has traditionally been an associated perioperative mortality of 25%–50%. There is little reliable evidence comparing embolectomy and thrombolytic therapy. Mortality rates have been found to be lower when using a surgical approach combining rapid diagnosis, prompt surgical intervention and a high frequency of concurrent IVC filter placement. [64]

Surgical embolectomy should therefore be strongly considered in patients with PE and hypotension who have absolute contraindications to thrombolytic therapy or if thrombolytic therapy has failed. [13] Embolectomy may also be useful when patients have free-floating intracardiac thrombus and a large patent foramen ovale. [65]

Concurrent Haemodynamic Support

Shocked patients with PE (high-risk PE) need urgent haemodynamic support in addition to attempts at embolus destruction and prevention of further embolisation.

Intravenous Fluids

Volume loading can improve haemodynamic status in patients with large PE, although if excessive then fluid therapy may worsen RV function which can in turn affect LV function and become detrimental. [66] Cautious administration of small amounts of intravenous fluid should occur.

Vasopressors

Embolus destruction (with thrombolytic therapy or embolectomy) reduces RV afterload and secondary RV dilatation and strain – reducing the myocardial oxygen demand. However, elevation of the systemic blood pressure in addition to a reduction in pulmonary and RV pressures may also be helpful in improving coronary blood flow, based on the rationale that the RV coronary perfusion pressure (RVCPP) can be severely impaired in large PE.

RVCPP is estimated by the formula:

$$\mathrm{RVCPP} = \mathrm{MAP} - \mathrm{RVPm} \tag{45.1}$$

where MAP is the mean arterial pressure and RVPm is the mean RV pressure, all in mmHg.

RVPm can then be estimated by the formula:

$$\mathrm{RVPm} = \mathrm{CVP} + 1/3\left(\mathrm{PAPs} - \mathrm{CVP}\right) \tag{45.2}$$

where CVP is the central venous pressure and PAPs is the systolic pulmonary arterial pressure, all in mm Hg.

When RVCPP falls as low as 30 mm Hg (4 kPa) (normal being around 70–80 mm Hg [9.31–10.64 kPa]), RV myocardial blood flow falls substantially and this contributes significantly to severe RV failure and shock. Efforts to elevate the MAP or reduce the PAPs should increase the RVCPP and therefore improve coronary blood flow to relieve ischaemia. Haemodynamic support for the shock state should therefore predominantly involve vasopressor drugs, as these will predominantly increase MAP and therefore RVCPP.

Norepinephrine (noradrenaline) is preferred to a pure alpha agonist such as phenylephrine as cardiac output and RV myocardial blood flow effects are greater owing to the added beta-adrenoceptor agonist action. Epinephrine (adrenaline) and vasopressin are reasonable alternatives to norepinephrine.

Although systemic vasodilators might improve the measured cardiac output in PE with haemodynamic instability, they may be harmful overall as the MAP will either fall or remain constant at best and therefore the RVCPP will not increase. Isoprenaline, dobutamine, nitroglycerin, nitroprusside or milrinone should be considered only if the MAP is adequate and treatment is focused on cardiac output or pulmonary artery pressure.

Extracorporeal membrane oxygenation (ECMO) is an alternative form of haemodynamic support that may be available in more specialised institutions. [67] It should be considered for patients with PE who have had cardiopulmonary arrest, have very severe shock or to support mechanical thrombectomy procedures.

Selective Pulmonary Vasodilators

Inhaled nitric oxide may be useful in patients with significant PE by selectively decreasing pulmonary arterial pressure with minimal effect on systemic haemodynamics. It may also assist in the severely hypoxaemic patient. Inhaled iloprost 2 hourly or continuous prostacyclin nebulisation is an alternative. [68]

There is a limited role for systemic pulmonary vasodilator therapy as first-line treatment. Discussion with the regional pulmonary hypertension service would be appropriate prior to commencing these treatments.

Other Supportive Management

Oxygen should be supplemented to target adequate oxygen saturation. High flows may be required because of hyperventilation and the increased dead space. Intubation and mechanical ventilation may be necessary.

If chest pain is prominent, opiate analgesia can be administered. It is useful to have at least a central venous catheter particularly before thrombolytic therapy is given. Although there is an increased risk of bleeding owing to the concurrent administration of thrombolytic therapy and/or anticoagulant therapy, this is probably outweighed by the importance of secure venous access and monitoring of the circulation in patients with haemodynamic compromise due to PE.

Prevention

Prophylaxis is probably the most important management aspect of VTE. All ICU patients should have an adequate assessment as to whether prophylaxis is warranted and how this should be delivered. [69] Careful attention to the intervention and dose is required as omission of prophylaxis [70] and failure of prophylaxis [71], [72] are common.

LMWHs or fixed low-dose subcutaneous UFH can be used for the prevention of VTE in critically ill patients. [72] Both therapies seem comparable for prophylaxis of DVT. Mechanical approaches (including graduated-compression stockings and intermittent pneumatic compression devices) [73] seem best utilised in patients who are bleeding or at major risk of bleeding. When bleeding risk decreases, pharmacological thromboprophylaxis should be commenced.

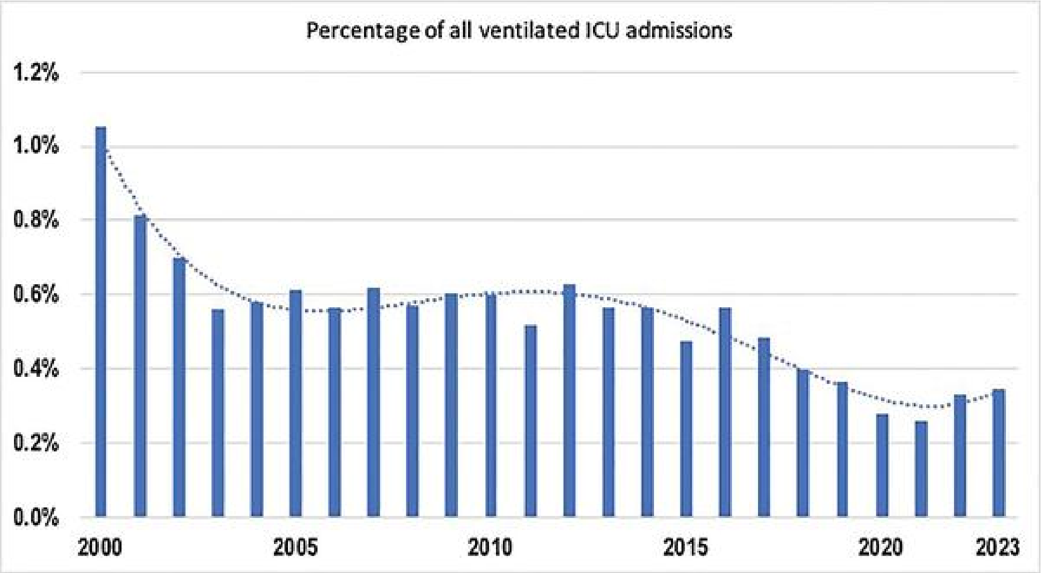
Acute severe asthma

David V. Tuxen, Mark Hew and Eve Denton

Acute severe asthma is a medical emergency associated with significant morbidity and mortality. Many of the adverse outcomes are attributed to underestimation of severity with delayed and/or inadequate treatment [1-3] and are potentially preventable.

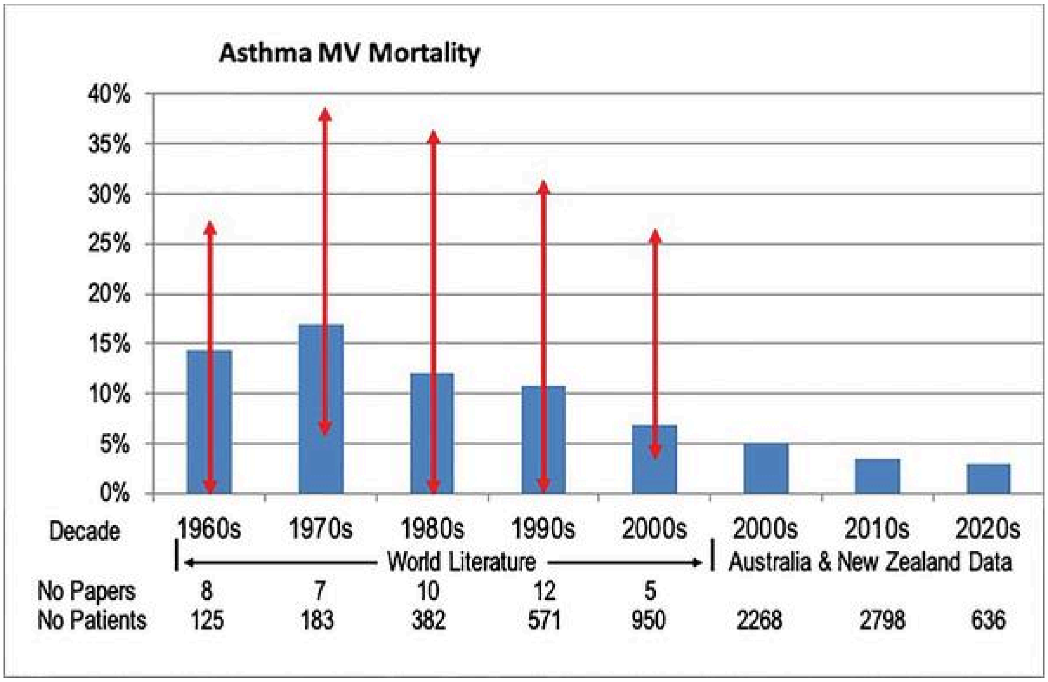
The worldwide prevalence of asthma varies widely with higher prevalence in middle- to high-income countries, particularly the UK, New Zealand and Australia (where 11% have chronic asthma), but higher mortality in low-income countries. [4-6] Between 1990 and 2019, the total prevalence of asthma worldwide increased but age-standardised prevalence rates decreased, meaning the increase was largely driven by population growth. There was significant variability between regions with a general trend toward increased incidence and prevalence in low to middle-income countries and stabilisation or reduction in high-income countries. [6,7]

In the 1970s and early 1980s, asthma-related hospitalisation and mortality increased, peaking in the mid-1980s. Since that time there has been a trend downward but over the past decade, there has been no further improvement. [6,8,9] The reduction in asthma mortality has been attributed to widespread guideline dissemination, better community management of asthma, [1,2] increasing use of inhaled corticosteroids, [3] non-pharmacological measures such as action plans and asthma education, and more widespread use of monoclonal biologics, targeting underlying inflammatory pathways. However, in 2015 almost half of asthma patients in Australia still had uncontrolled asthma, and gains from improved community management appear to have stalled. [10] Improved intensive care asthma management has resulted in less requirement for mechanical ventilation (Fig. 46.1) and decreasing mortality for those who did require mechanical ventilation (Fig. 46.2).[8, 9] These changes have resulted in the group of asthma patients who require mechanical ventilation having more severe, treatment-refractory asthma.[11, 12] Significant and potentially preventable mortality continues to occur in those patients who do require intensive care or mechanical ventilation.[11, 13, 14] At the same time, mortality rates in Australia due to asthma have not fallen further in the last ten years, with approximately 500 deaths per year attributable to asthma.[15] An audit of asthma deaths[16] reported to the coroner suggests that social and behavioural determinants may have contributed to these deaths as much as severe asthma biology. Fundamental systemic changes[17] may need to be applied to asthma care to address these patient factors and deliver further improvements in asthma control, severe exacerbation risk and mortality rates.[18]



The bar graph displays the percentage of all ventilated intensive care unit admissions from 2000 to 2023. The vertical axis represents percentage from zero percent to one point two percent. The horizontal axis lists years at regular intervals from 2000 to 2023. The graph shows a high percentage near one percent in 2000, followed by a downward trend over time. Bars for the mid-2000s to early 2010s remain relatively steady with minor fluctuations. From 2015 onward, a gradual decline is visible, which reaches the lowest values around 2021, with a slight increase noted by 2023. A dotted line indicates the overall trend.

FIG. 46.1 ICU admissions for acute asthma as a percentage of all intensive care admissions in Australia and New Zealand extracted from the ANZICS Adult Patient Database for the period 2000 to September 2023. (Courtesy The ANZICS Centre for Outcomes and Resources Evaluation (CORE).)



The bar chart presents asthma mechanical ventilation mortality percentages over decades from 1960s to 2020s. The vertical axis represents percentages from zero percent to forty percent. The horizontal axis categorises data by decades, divided into world literature for 1960s through 1990s and Australia and New Zealand data from 2000s through 2020s. Mortality percentages are highest in earlier decades, approximately fifteen percent in 1960s and 1970s, which decreases in each following decade. By 2000s the percentage drops below ten percent and continues to decline through 2010s and 2020s. Arrows above each bar represent ranges in reported mortality. The number of research papers and patients per decade is listed below each column, with eight papers and one hundred twenty five patients in 1960s and one paper with six hundred thirty six patients in 2020s.

FIG. 46.2 Mortality rates for patients with acute asthma who required mechanical ventilation. International publications from 1960 to 2010 are grouped by decade with mortality shown as mean with minimum and maximum mortality within the reported series for that decade. Mortality data from all intensive care admissions in Australia and New Zealand extracted from the ANZICS Adult Patient Database for the period 2000 to September 2023, also grouped by decade. (Courtesy The ANZICS Centre for Outcomes and Resources Evaluation (CORE).)

Clinical Definition

Asthma is a chronic inflammatory disease of the airways, defined by a history of respiratory symptoms such as wheezing, shortness of breath, chest tightness and cough that vary over time and in intensity, together with variable expiratory airflow limitation.[19], [20] It is now recognised that asthma is a heterogeneous disease, and distinct inflammatory phenotypes[21] have been described. Exacerbations of asthma are characterised by increasing symptoms and decreased expiratory airflow. Status asthmaticus is not well defined; however, for practical purposes, it is any patient unresponsive to initial doses of nebulised bronchodilators.[22]

‘Difficult’ (as opposed to ‘severe’) asthma is another term in which patients can present with mild, moderate or severe asthmatic symptoms. Characteristics include (1) discordance between symptoms and objective markers of asthma such as lung function or arterial blood gases, (2) severe asthma despite treatment that should be effective, (3) a disconnection between patient expectations and effective outcomes.[23] Commonly, there is poor compliance with inhaled corticosteroids, psychosocial adversity and secondary gain with continued symptoms. Significant anxiety, social and adverse family circumstances frequently coexist. Differential diagnoses include hyperventilation syndromes, vocal cord dysfunction, COPD or the presence of treatment non-adherence (estimated to occur in two-thirds of patients presenting). These patients are difficult to treat because they may have severe life-threatening asthma, due to poor compliance with their usual medication.

Aetiology

The pathogenesis of asthma reflects a complex interaction between environmental and genetic influences. In developed nations, reduced exposure to childhood infections and changes in dietary patterns may alter gut, respiratory, and skin bacterial composition and diversity (the microbiome), which then increases the risk of developing allergic diseases including asthma. [24] This may be mediated through effects on T cell inflammatory gene transcription which promote activation towards a T helper 2 phenotype, driving the allergic inflammatory response. [25] Such epigenetic changes have been found in asthma patients, and also impair their responsiveness to corticosteroid therapy. [26] These persistent changes may also be passed on to subsequent generations, thus explaining the continuing rise in allergic disease prevalence. [25]

IgE-dependent mechanisms appear to be important in generating the characteristic state of airway inflammation and bronchial hyperreactivity with the allergens in the local environment dictating the specificity of the antibody response. [27] An additional asthma phenotype which increases the risk of exacerbations is eosinophilic asthma, defined either by blood or sputum eosinophilia, and often elevated exhaled nitric oxide. [21] Asthma comorbidities [28] such as obesity and chronic rhinosinusitis also predispose to exacerbations. Triggers of acute asthma can be non-specific (cold air, exercise and atmospheric pollutants), specific allergens (house dust mites, pollen and animal danders), modifiers of airway control (aspirin and beta blockers) or stress or emotion. No precipitant can be identified in over 30% of patients with acute asthma exacerbations.

A wide range of risk factors for life-threatening asthmatic episodes and/or the need for mechanical ventilation is now recognised. First is *underestimation of severity* , with delayed and/or inadequate treatment by managing doctors and/or the patient. [1-3] Second, *patient behaviour factors* that are associated with the requirement for intensive care [29] and mechanical ventilation are smoking (and illicit drugs), [29] poor treatment compliance, prior treatment with beta-agonists without inhaled steroids. [11], [30] Low socioeconomic status has also been recognised as a risk factor, as has ethnic minority status. [31] Third, *genetic polymorphism* (the IL4RA*576R allele) is now recognised as a significant factor related to fatal or near-fatal asthma attacks. [12, 32] Other functional factors linked to severe asthma attacks include airway remodelling, down-regulation of β-receptors, and lack of steroid responsiveness. [12] Diminished perception of dyspnoea in some patients with acute severe asthma leads to delayed interventions. [12, 33]

Pathophysiology

The post-mortem airway pathology of patients who die from acute asthma includes bronchial wall thickening from oedema and inflammatory cell infiltrate, hypertrophy and hyperplasia of bronchial smooth muscle and submucosal glands, deposition of collagen beneath the epithelial basement membrane and prominent intraluminal secretions. These secretions may narrow or occlude the small airways, and post-mortem studies frequently report extensive mucus plugging and atelectasis. [34, 35] When interpreting the latter findings, it is important to remember that during life in very severe asthma, the lungs are hyperinflated to close to total lung capacity (TLC) by maximal inspiratory effort and beyond TLC during mechanical ventilation. At this time radiological atelectasis is rare, suggesting that most airways are communicating at these high lung volumes, even if airways are very narrowed. Only at death does the prolonged apnoea allow lung deflation, widespread airway closure and alveolar gas absorption to give the post-mortem appearance of extensive complete occlusion that was not present to the same degree during life.

In some deaths, bronchial mucus is absent; in these cases, airway obstruction may be mainly due to intense smooth bronchoconstriction. This observation may account for two patterns of progression of asthma:

1. Acute severe asthma is the commonest group (80%–90%), with progression of symptoms over many hours or days, often with a background of poor control and recurrent presentations. Most patients in this group are female, with upper respiratory infections being frequent triggers; they respond more slowly to treatment,

which may reflect greater contribution from mucous inspissation and chronic bronchial wall inflammation with eosinophilia.[33, 36]

2. ‘Hyperacute’, ‘fulminating’, ‘asphyxic’ or ‘sudden onset’ severe asthma is where the interval between onset of symptoms and intubation is less than 3 hours.[33, 36-38] This presentation is less common (approximately 10%–20% of life-threatening presentations), tends to occur in younger patients with relatively normal lung function but high bronchial reactivity, and the majority of patients are male. Massive respiratory allergen exposure, cold air or exercise and psychosocial stress are the most frequent triggers.[33] Although patients in this group were becoming less common due to the widespread use of inhaled corticosteroids, ‘epidemic thunderstorm asthma’ due to the massive production and distribution of allergens has been documented. Thunderstorm asthma events have occurred internationally, but Australia has reported as many events as the rest of the world combined with over 5 times the number of patients affected and 10 deaths from one particular event (Fig. 46.3). Four of the seven epidemics have occurred in Melbourne during the peak of the ryegrass pollen season. The causative allergen underlying events in Southeast Australia has been ryegrass pollen, while other pollens and fungal spores have been implicated in events elsewhere.[39, 40]

10 deaths	

The list is depicted in a two-column table titled Thunderstorm Asthma and compares international and Australian reports. The left column labelled International Reports lists eight events from July 1983 to December 2016. Locations include Birmingham, Atlanta, London, Canada, Naples, Athens, Ahvaz, and Kuwait. Patient numbers are shown for London with six hundred forty patients, Ahvaz with two thousand patients, and a note of one death in London. The right column labelled Australian Reports includes seven events from November 1987 to November 2016. Locations include Melbourne, Tamworth, Wagga Wagga, and Canberra. The November 2016 Melbourne event notes nine thousand nine hundred patients and ten deaths. A highlighted line under the November 2010 Melbourne entry states no deaths so far.

FIG. 46.3 A comparison of reports of thunderstorm asthma outside and inside Australia including the year and location of the event, and, if reported, the month of the event and number affected.

The characteristic pathology of asthma leads to increased airway resistance and dynamic pulmonary hyperinflation. This has a number of consequences:

- *Increased work of breathing* results from increased airway resistance and reduced pulmonary compliance as a result of high lung volumes. When asthma is severe, dynamic hyperinflation may bring the lung volume close to total lung capacity.[39] This causes a severe mechanical disadvantage of inspiratory muscles with diaphragm flattening and results in a large inspiratory muscle effort affecting a small change in inspiratory pressure. The final outcome can be respiratory muscle failure with insufficient alveolar ventilation and consequent hypercapnia.[41]
- *Ventilation–perfusion mismatch* is the result of airway narrowing and closure. This leads to impaired gas exchange and increases the minute ventilation requirement, further adding to the work of breathing.[41]
- *Adverse cardiopulmonary interactions* are seen when the marked changes in lung volume and pleural pressure impact the function of both left and right ventricles.[42,43] Spontaneous breathing during acute asthma can generate inspiratory pressures as low as −35 cm H_2O.[42,43] This increases venous return to the right ventricle (RV) and increases RV volume during inspiration. However, increased RV afterload as a result of hypoxic pulmonary vasoconstriction, acidosis and increased lung volume[42,43] with increased pulmonary capacitance decrease return to the left ventricle (LV). These negative intrapleural pressures also cause increased LV afterload[42,43] and increased RV afterload with septal shift, reduces LV volume[42,43] further reducing LV output during inspiration. Pulsus paradoxus is the most direct result of these cardiopulmonary interactions in severe asthma. Pulsus paradoxus is a decrease in systolic blood pressure during inspiration of >10 mm Hg, typically 15–25 mm Hg (normal ≤ 5 mm Hg). The degree of pulsus paradoxus may not correlate with the

severity of asthma as it may be reduced by inspiratory muscle weakness or fatigue.

Clinical Features and Assessment of Severity

The symptoms of asthma are well known and include wheezing, cough, dyspnoea, and chest discomfort or tightness. Triage and assessment of severity of the acute asthma attack are crucial. Underestimation or non-measurement of asthma severity is associated with increased mortality. [44] Assessment has two key features: assessment of initial severity and ongoing assessment of response to treatment:

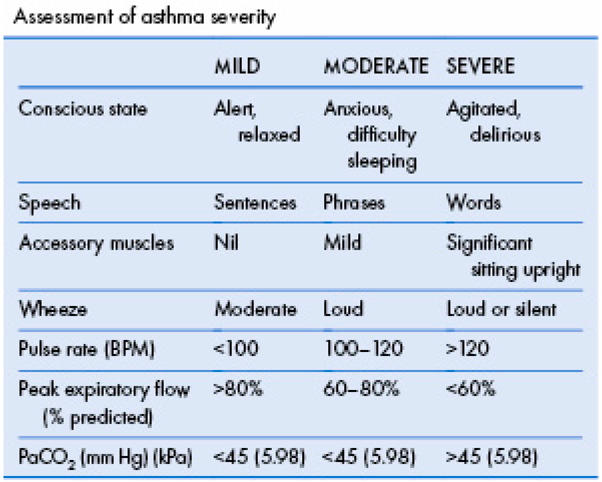
History

Any history of prior intubation and mechanical ventilation for asthma is a predictor for life-threatening asthma. [44] A history of poor asthma control, multiple recent medical presentations for asthma and poor response to prior treatments are recognised risk factors. Other risk factors are listed above (see aetiology).

Physical Examination

General appearance and level of distress can be an important indicator of severity (**Table 46.1**). Use of accessory muscles, suprasternal retraction, markedly diminished breath sounds or a silent chest, central cyanosis, inability to speak, a disturbance in the level of consciousness, upright posture and diaphoresis all suggest a severe attack. A respiratory rate of >30/min, pulse rate >120/min and pulsus paradoxus of >15 mm Hg are associated with severe asthma though their absence does not preclude life-threatening asthma. Patients with diminished perception of dyspnoea may mask severe asthma and lead to underestimation of severity. [33]

Table 46.1



Assessment of asthma severity

	MILD	MODERATE	SEVERE
Conscious state	Alert, relaxed	Anxious, difficulty sleeping	Agitated, delirious
Speech	Sentences	Phrases	Words
Accessory muscles	Nil	Mild	Significant sitting upright
Wheeze	Moderate	Loud	Loud or silent
Pulse rate (BPM)	<100	100–120	>120
Peak expiratory flow (% predicted)	>80%	60–80%	<60%
$PaCO_2$ (mm Hg) (kPa)	<45 (5.98)	<45 (5.98)	>45 (5.98)

Pulsus paradoxus when present indicates severe asthma; however, it is an unreliable test.

Ventilatory Function Tests

The patient may not be able to perform these due to breathlessness. However, FEV_1 and peak expiratory flow rate (PEFR) are useful indicators of severity and response to treatment when done serially. An FEV_1 <1.0 litre or PEFR <100 L/min indicates very severe asthma at significant risk of requiring mechanical ventilation. In some patients forced expiration may worsen symptoms; these measurements should cease if this occurs.

Pulse Oximetry

Pulse oximetry is usually readily available and provides a rapid assessment of oxygenation. It is also very valuable in regulation of oxygen therapy, both for avoiding hypoxaemia (SpO_2 <90%)[45] and for avoiding potential side effects of excessive oxygen (SpO_2 >95%).[46] Pulse oximetry cannot assess arterial $PaCO_2$ or acid–base state and so does not replace the need for blood gases.

Arterial Blood Gases

Arterial hypoxaemia is usually present in a patient with severe asthma breathing room air, though it tends to respond well to moderate oxygen supplementation (28%–35%).[45] Blood gases should not delay initiation of treatment, and are not required in mild asthma or moderate asthma that is responding well to treatment. They are very important in severe asthma or moderate asthma with inadequate treatment response. The $PaCO_2$ is an important measure of severity and, if hypercapnia is present, an important guide to treatment response. Venous blood gases have had increasing use in place of arterial blood gases. Such blood gases will usually determine the upper limit of $PaCO_2$ and lower limit of pH, however, there is insufficient agreement between venous and arterial PCO_2 measurements to determine the degree of hypercapnia in obstructive airway disease.[47] Observing the SO_2 in peripheral venous blood ($SpvO_2$) gas can reduce this discrepancy. The $SpvO_2$ can vary widely. When the $SpvO_2$ is close to the oximetry saturation, then $PaCO_2$ levels will be similar to the $PvCO_2$. When $SpvO_2$ close to the usual central SvO_2 range (65-75%), the $PaCO_2$ will be approximately 5 mmHg below the $PvCO_2$. Lower levels of $SpvO_2$ will have increasing larger differences between arterial and venous PCO_2. We therefore recommend arterial blood gas measurement in the assessment of acute severe asthma, where initial and follow-up PCO_2 levels inform critical treatment decisions.

Ventilation is initially increased in an acute attack leading to hypocapnia and a respiratory alkalosis.[45] As the asthmatic attack worsens, the work of breathing, V / Q mismatch and adverse cardiopulmonary interactions all increase, and the minute ventilation required to maintain the same alveolar ventilation and $PaCO_2$ increases. There are two contributory factors to development of hypercapnia - dynamic hyperinflation and muscle fatigue. It is important to discriminate between these two causative factors as they can have different time courses and different risks for intubation that do not correlate with the $PaCO_2$ level (see Invasive Ventilation section, this chapter). Rapid very severe asthma can result in dynamic hyperinflation close to TLC where insufficient minute ventilation results from mechanical limits on inspiration and expiration. Marked hypercania ($PaCO_2$ >60-70) may occur before much fatigue has occurred and may improve with prompt bronchodilator treatment avoiding intubation. Prolonged moderately severe asthma can result in muscle fatigue with $PaCO_2$ rising to lower levels but with a higher risk of requiring intubation. Discrimination between these causes is done via careful evaluation of the time over which symptoms developed and clinical assessment of fatigue. A normal $PaCO_2$ in a patient with acute asthma may be a concerning sign of impending respiratory decompensation. The presence of hypercarbic acidosis is associated with a FEV_1 of <20% predicted and reliably indicates that asthma is severe. A metabolic acidosis may also be present, and this is most commonly due to hyperlactatemia associated with intravenous or continuous nebulised beta-agonists.[48, 49]

Chest X-Ray

Chest X-rays are not generally helpful in assessing severity and are not routinely indicated. A chest X-ray should be performed when asthma is severe or refractory to treatment, when barotrauma or lower respiratory tract infection is suspected or when the diagnosis is in doubt. It is not required in milder attacks that respond well to treatment.

Assessment of Treatment Response

Ongoing evaluation of response to therapy is critical. The response to the first 2 hours of treatment is an important predictor of outcome.[50] Adverse events are associated with underestimation of severity, inadequate observation after initial assessment and under-treatment. Evaluation should include repeated assessments of (1) appearance and physical indicators of severity (see Table 46.1); (2) objective measurements – FEV1 or PEFR, heart rate, respiratory rate, pulsus paradoxus; (3) SpO_2 and oxygen requirements; (4) progress of $PaCO_2$ or metabolic acidosis if present on blood gases.

Admission to intensive care is preferred for severe asthma. Indications for immediate admission to intensive care include respiratory arrest, altered mental status, dysrhythmias or associated myocardial ischaemia.

Differential Diagnosis

The diagnosis of asthma is usually obvious. However, wheezing and dyspnoea may be caused by other illnesses, including left ventricular failure, aspiration, upper airway obstruction, inhaled foreign body, pulmonary embolism or hyperventilation syndromes. Wheeze and dyspnoea arising in hospitalised patients who were not admitted with asthma are less likely to be due to asthma. Clues to another or additional diagnosis include (1) no past history of asthma; (2) sudden onset following vomiting or food intake; (3) focal or asymmetrical chest auscultation findings; (4) risk factors for thromboembolism; (5) onset during hospitalisation when admitted with another condition.

Management

Established Treatments

The Global Initiative for Asthma produces annually updated international guidelines for asthma management, including acute management. [51] Initial therapy of acute severe asthma should include the following.

Oxygen

Hypoxaemia contributes to life-threatening events that complicate acute severe asthma. [52] Current guidelines [53] recommend supplemental oxygen should be titrated to achieve a SpO_2 of 94%-98%, but clinicians should consider the risk of oxygen-induced increasing hypercapnia with coexisting chronic airflow limitation or pre-existing chronic hypercapnia. This phenomenon was not believed to be relevant to the majority of patients with acute asthma; however, there is now emerging evidence that hyperoxia may be harmful to a more widespread group [54] by releasing pulmonary hypoxic vasoconstriction, worsening V / Q matching and increasing hypercapnia. A previous trial [46] showed a decrease in $PaCO_2$ in a group receiving 28% O_2 and an increase in $PaCO_2$ in a group receiving 100% FiO_2. A more recent trial [55] demonstrated patients receiving oxygen titrated to achieve target

SpO_2 of 93-95% had lower transcutaneous CO_2 levels after one hour than those receiving 8L O_2/min by mask.

Beta-Agonists

Short-acting beta-agonists remain the first-line bronchodilator therapy of choice.[53,56] Agents include salbutamol (albuterol), terbutaline, isoproterenol (isoprenaline) and epinephrine (adrenaline). Salbutamol is generally the agent of first choice as it has relative β_2-selectivity, with decreased β_1-mediated cardiac toxicity. Long-acting beta-agonists such as salmeterol have no role in status asthmaticus owing to the slow onset of action and association with fatalities in this setting.[22] Beta-agonists cause bronchodilatation by stimulation of β_2-receptors on airway smooth muscle and may reduce bronchial mucosal oedema.

The standard approach is to start with nebulised salbutamol in high and repeated doses. The typical adult dose is 5–10 mg (in 2.5–5.0 mL diluent volume) every 2–4 hours, but more frequent doses with a higher total dose are often required in severe asthma. It should be noted that less than 10% of the nebulised drug reaches the lung even under ideal conditions.[57] Continuous nebulisation appears to be superior to intermittent doses and is commonly used at the beginning of treatment in severe asthma.[22,58] The nebuliser should be driven by air or oxygen (if hypoxic) with the flow at 10–12 L/min and a reservoir volume of 2–4 mL so as to produce particles in the desired 1–3 µm range.[59] The total dose should be modulated by the response to treatment and the level of toxic side effects.

Beta-agonists can also be delivered by metered dose inhaler (MDI). There are data to suggest that, in non-intubated patients, MDIs combined with a spacing device are as effective as or more effective than nebulisers and are cheaper to use.[60] In intubated patients, both nebulisers and MDIs have been used effectively.[61] Two-thirds of acutely presenting patients will respond well to inhaled beta-agonists[62] irrespective of the method of administration. The remaining one-third are refractory even to high doses and usually require longer periods of intense treatment including multiple other agents.

Intravenous beta-agonists remain controversial. There is no clear evidence of benefit[63] and significant side effects. Despite this, intravenous beta-agonists have a theoretical benefit of additional access to lung units with severe airflow obstruction and poor nebulised drug delivery and some studies have demonstrated improved response when intravenous beta-agonist is used.[64] Intravenous beta-agonists continue to be considered if the patient is not responding to continuous nebulisation.[65] The typical dose is 5–20 µg/min, but doses >10 µg/min should be used with caution because of side effects, which should be monitored closely. Salbutamol 100–300 µg may also be given intravenously to non-intubated patients in extremis or delivered down an endotracheal tube should there be no time to gain intravenous access.

Side effects of beta-agonists include tachycardia, dysrhythmias, hypertension, hypotension, tremor, hypokalaemia, worsening of ventilation–perfusion mismatch and hyperglycaemia,[66] but the most common side effect of parenteral beta-agonists are occasionally seen with continuous nebulised beta-agonists is lactic acidosis. This occurs in over 70% of patients, has an onset within 2–4 hours of commencing an infusion or following an intravenous statim dose, levels may reach 4–12 mmol/L and may significantly add to respiratory distress.[49,67,68] Parenteral infusions should be initially limited to 10 µg/min and statim doses should not exceed 250 µg. Serum bicarbonate and lactate should be regularly monitored. If lactic acidosis becomes significant, the salbutamol infusion should be reduced or ceased. Lactic acidosis will generally resolve within 4–6 hours of infusion cessation and is seldom a problem with infusions in place for more than 24 hours.

Long-term high-dose beta-agonist use has been associated with increased mortality,[69] but whether high-dose beta-agonists are a marker of disease severity, an indicator of suboptimal inhaled steroids or a direct cause of death is unclear. These concerns do not apply to the treatment of the acute asthma attack.

Anticholinergics

Anticholinergics cause bronchodilatation by decreasing parasympathetic-mediated cholinergic bronchomotor tone. Ipratropium bromide is the most commonly used anticholinergic for asthma and is a quaternary derivative of atropine. Although some conclude there is insufficient evidence, [70] a number of studies and meta-analyses suggest clear additional benefits and few side effects when ipratropium bromide is added to the beta-agonist regimen although the benefit appears to be limited to the first 24 hours of use. [71], [72] Ipratropium is now widely used as first-line therapy for acute severe asthma in conjunction with beta-agonist therapy. Preservative-induced bronchoconstriction has been reported in a few patients and can be prevented by using preservative-free solutions. [73] The bronchodilatation effect of ipratropium bromide appeared to be maximal with a dose of 250 µg when studied in children between 9 and 17 years of age. The optimal dose is not known in adults; a reasonable regimen would be to add 500 µg of ipratropium bromide to the salbutamol nebuliser every 2–6 hours; however, initial dose intervals as low as 10–20 minutes have been recommended. [74]

Corticosteroids

The role of corticosteroids in the acute asthma attack has been well established. Systemic steroids should be considered in all but mild exacerbations of asthma. [75] Their benefits include increased β-responsiveness of airway smooth muscle, decreased inflammatory cell response and decreased mucus secretion. Early treatment with corticosteroids has been shown to decrease the likelihood of hospitalisation and decrease the mortality rate from acute asthma. Systematic reviews [75], [76] suggest that effects commence within 6–12 hours, that oral is as effective as intravenous, and that there is little evidence of benefit for initial daily doses exceeding 800 mg/day of hydrocortisone (160 mg/day methylprednisolone) given in four divided doses.

Inhaled steroids have established long-term benefits and are believed to be a major factor in asthma mortality reduction. [1-3] Although some believe there is insufficient evidence, [70] there are data that inhaled steroids may also have a role during an acute attack [77], [78] and it appears reasonable to use them routinely from day one as they may also enable more rapid dose reduction of parenteral steroids, potentially reducing side effects.

Parenteral corticosteroid dose reductions should commence after 1–3 days according to the severity of the attack, the degree of chronic inflammation and the response to treatment and should be converted to a reducing dose of oral steroids within 4–7 days (e.g. oral prednisolone starting at 40–60 mg per day).

Side effects of corticosteroids include hyperglycaemia, hypokalaemia, hypertension, acute psychosis and myopathy,[79], [80] though they are usually well tolerated acutely. The immunosuppressive effects can increase the risk of infections including *Legionella* , *Pneumocystis carinii* and varicella,[81], [82] especially when the patient is on long-term corticosteroids. Allergic reactions including anaphylaxis have been reported with the use of most corticosteroid preparations.

Magnesium Sulphate

Magnesium sulphate is postulated to block calcium channels, and possibly acetylcholine release at the neuromuscular junction, leading to smooth muscle relaxation and bronchodilatation. It appeared to be well tolerated in early studies, and a number of prospective, randomised, double-blind, prospective trials in adults with acute asthma were performed with conflicting results.

The most recent Cochrane reviews[83], [84] on this topic suggest that intravenous magnesium is useful for adults with acute severe asthma, although evidence for benefit in children is less clear. If given, recommended doses for adults are 5–10 mmol (1.25–2.5 g, 2.5–5.0 mL of 50% solution) given slowly over 20 minutes, but doses up to 40–80 mmol (10–20 g) have been given.[85] Side effects include hypotension, flushing, sedation, weakness, areflexia, respiratory depression and cardiac arrhythmias seen at higher serum levels (>5 mmol/dL or 12 mg/dL). Serum concentrations should be measured if repeated or high doses are used.

Aminophylline

There have been conflicting reports regarding the efficacy of aminophylline in acute asthma, ranging from no benefit to improved lung function and improved outcome. However, it is accepted that aminophylline is an inferior bronchodilator, with a narrow therapeutic range and frequent side effects,[86] including headache, nausea, vomiting and restlessness, with cardiac arrhythmias and convulsions that can occur at serum levels above 200 µmol/L (40 mg/L). A Cochrane meta-analysis[87] identified no patient subgroup in which aminophylline was beneficial.

As a result, aminophylline is not a first-line treatment.[53,56,70] Aminophylline may be given to patients with acute asthma who are not showing a favourable response to full treatment with first-line agents. Careful administration and monitoring are required with an initial loading dose of 3 mg/kg (maximum 6 mg/kg, omitted if the patient is already taking oral theophylline) and an infusion of 0.5 mg/kg/h. This should be reduced in patients with cirrhosis, cardiac failure or chronic obstructive airway disease and in patients taking cimetidine, erythromycin or antiviral vaccines. Drug levels should be taken after a loading dose (if given), and then 24 hours later aiming for a level of 30–80 µmol/L (5–12 mg/L). Levels should be repeated daily thereafter until stability has been achieved. The duration should be based on the response to treatment.

Non-Established Treatments

A number of other therapies have reported benefits in acute severe asthma, but their role in addition to full standard therapy has not been clearly established and they are not advocated for routine use. However, these modes of therapy can be considered in the patient who is in extremis or remaining severe despite conventional treatment.

Adrenaline

Adrenaline has some theoretical advantages over pure β_2-agonists in that its additional α-agonist actions of vasoconstriction and mucosal shrinkage may improve airway calibre. However, in practice, nebulised adrenaline has not been shown to confer any advantage over nebulised β_2-agonists and is not recommended because of its cardiac side effects.[74] It may be tried on the patient who is failing to respond to conventional treatment. The nebulised dose is 2–4 mg in 2–4 mL (1% solution, 0.05 mL/kg) 1–4-hourly. Epinephrine by infusion may avert mechanical ventilation in very severe cases but should be used with caution with ECG monitoring and preferably with central venous access. An initial intravenous dose of 0.2–1.0 mg (2–10 mL of 1:10,000 epinephrine) is given slowly over 3–5 minutes. This may be followed by a continuous infusion of 1–10 µg/min, which is weaned when the acute attack subsides.[88]

The one situation where adrenaline is indicated is when acute severe bronchospasm is suspected to be caused by anaphylaxis. Intramuscular adrenaline should be administered immediately at a dose of 0.3–0.5 mg (0.3–0.5 mL of 1:1000 epinephrine), repeated if necessary 1–2 times over 5–10 minutes. If there is no improvement, consider intravenous epinephrine as above.

Heliox

Inhalation of helium:oxygen mixture reduces gas density and turbulence with reduced airflow resistance. The most effective gas mixture is 70% helium (30% oxygen) and the minimum concentration likely to provide benefit is 60% helium. Work of breathing is decreased and pulmonary access to inhaled bronchodilators may be improved.[89,90] Meta-analyses[91,92] have shown trends towards improved aspects of lung function but insufficient evidence to recommend use of heliox in severe asthma. However, it otherwise appears safe and may be tried in critical asthma to avert intubation or during difficult mechanical ventilation provided the patient can tolerate 30%–40% O_2.

Anaesthetic Agents

Ketamine, a dissociative anaesthetic agent, has been used in severe asthma. It may cause bronchodilatation by both sympathomimetic potentiation and a direct effect on airway smooth muscle.[93] Small case series have suggested some benefit, although randomised controlled trials have shown mixed results[94,95] and a recent systemic review of the available trials concluded that there was significant heterogeneity in studies (both with regard to population and ketamine administration protocol) and that there was no clear benefit in acute asthma.[96] Ketamine may be a useful induction agent for endotracheal intubation (dose 1–2 mg/kg) as it may ameliorate the bronchoconstrictor response to intubation. It has been used as a continuous infusion in the dose range of 0.5–2 mg/kg/h [94] to treat refractory asthma. Side effects include increased bronchial secretions, a hyperdynamic cardiovascular response and hallucinations; the hallucinations can be reduced with concomitant benzodiazepines.

The volatile inhalational agents including halothane, isoflurane and enflurane have been used in mechanically ventilated patients with severe asthma. [97] Clinical data are limited to small case series, and side effects include direct myocardial depression, arrhythmias and hypotension. [98] The volatile anaesthetic agents should be used with great care and usually only as a prelude to or during invasive ventilation. An anaesthetic machine or custom-fitted ventilator is required for safe administration.

Leukotriene Antagonists and Monoclonal Biologics

Leukotriene antagonists have shown benefits in chronic asthma [99] and there is some evidence of benefit in acute asthma although these data are insufficient to recommend its use. [70], [100] Monoclonal biologics targeting underlying allergic or eosinophilic inflammation are of significant benefit in the chronic management of severe asthma but their role in acute asthma is undetermined. [101-103]

Bronchoalveolar Lavage

Bronchoalveolar lavage has been used in severe refractory asthma to clear mucous plugging during mechanical ventilation. [104] It may have a role in ventilated patients with resistant mucus impaction, but it is rarely used.

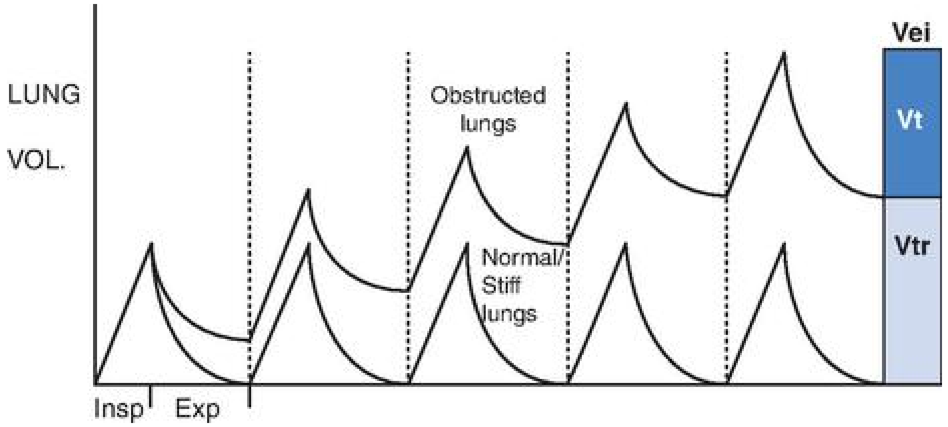
Therapies Not Recommended

Antibiotics are not routinely indicated [105] unless there is clear evidence of infection. Antihistamines are not effective. Inhaled mucolytics have been shown to have no benefit and may worsen airflow obstruction. Sedation is unsafe in acute asthma. There is a clear association between their use and avoidable deaths. [106] Patients with severe asthma should not be sedated unless being intubated and ventilated, or in carefully monitored circumstances.

Mechanical Ventilation in Asthma

Dynamic Hyperinflation

In all degrees of airflow obstruction, slow expiratory airflow results in incomplete exhalation of gas during normal expiratory times. Gas is trapped in the lungs by the arrival of the next breath and the lungs are unable to return to their normal passive relaxation volume (functional residual capacity, FRC). Incomplete exhalation of each successive breath causes progressive accumulation of trapped gas called dynamic hyperinflation (DHI) (Fig. 46.4), [107] which continues until an equilibrium point is reached where the exhaled volume increases to match the inspired volume. [107] This equilibrium occurs because increasing lung volume increases small-airway calibre and lung elastic recoil pressure, both of which improve expiratory airflow and allow the inspired tidal volume to be exhaled in the expiratory time available. There are three primary determinants of this equilibrium point: the volume inspired (V_t), the time for expiration (t_e which depends on both the ventilator rate or cycle time and the inspiratory flow or inspiratory time, t_i) and, the severity of airflow obstruction (the time constant of the lung). The first two determinants are controlled by the ventilator settings and compound to the minute ventilation (V_e), making this the most important determinant of DHI.

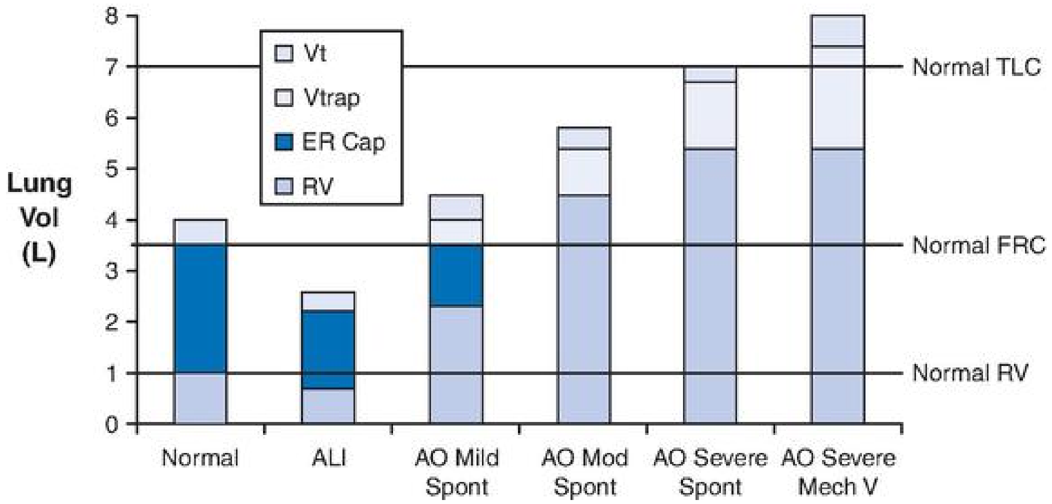


The line graph displays lung volume changes across inspiration and expiration cycles for different lung conditions. The waveform for normal stiff lungs shows symmetrical rise and fall, while obstructed lungs exhibit prolonged expiration and irregular patterns. The right side includes a colour-coded bar with three segments, which are total inspired volume, tidal volume, and trapped residual volume. The illustration contrasts the breathing patterns and volume distribution across varying lung compliance and resistance.

FIG. 46.4 Dynamic hyperinflation. The volume history of normal or acutely injured lungs compared with that of obstructed lungs when commenced on controlled mechanical ventilation. This shows initial lung volume to be at the passive relaxation volume of the respiratory system or functional residual capacity (FRC).

Gas trapped at the end of expiration exerts a positive pressure on the alveoli; this pressure is intrinsic positive end-expiratory pressure (PEEP$_i$) or auto-PEEP.[107, 108] During expiration, sequential closure of the most severely obstructed airways occurs with only the less obstructed airways remaining in communication with the central airway at the end of tidal expiration.[109] As a consequence, measured PEEP$_i$ underestimates the true magnitude of PEEP_i and is recognised as being insensitive to changes in severity.[109]

In mild airflow obstruction, this process is adaptive as it allows the desired minute ventilation, which could not be achieved at FRC, to be achieved at a higher lung volume (Fig. 46.5 , mild AO’). As asthma becomes more severe (Fig. 46.5 , ‘mod AO’) the static FRC that would be reached with a long expiratory time is elevated above the normal FRC by airway closure (static hyperinflation) and DHI further increases lung volume to a level where work of breathing is increased by lower lung compliance and respiratory muscles become less efficient from shortening and mechanical disadvantage. At this level, some degree of dyspnoea is expected. When asthma is severe enough to risk requiring mechanical ventilation, static hyperinflation may increase FRC by 50%[108] and very little DHI is required to reach TLC (Fig. 46.5 , ‘severe AO’). In this circumstance, the minute ventilation required to maintain normocapnia would cause hyperinflation beyond normal TLC. During spontaneous ventilation, the patient with severe asthma is unable to exceed TLC (Fig. 46.5), has a much lower maximum minute ventilation capacity and as a result must become hypercapnic even at maximum respiratory effort with no fatigue.[110] When mechanical ventilation is commenced, increased tidal volume and rate delivery are easily able to increase minute ventilation and DHI well beyond normal TLC (Fig. 46.5).[107] The consequences of this are commonly hypotension (due to increased intrathoracic pressure and decreased venous return) and barotrauma.[107, 110-112]



The stacked bar graph compares lung volume components, such as tidal volume, trapped volume, expiratory reserve capacity, and residual volume, across conditions, which include normal lungs, acute lung injury, and acute obstruction of varying severity and ventilation modes. Bars progressively increase in total height from normal to severe obstruction with mechanical ventilation, which shows elevated total lung capacity, functional residual capacity, and residual volume in more severe disease states.

FIG. 46.5 Comparison of lung volumes in patients with normal lungs, acute lung injury (ALI), and mild, moderate and severe airflow obstruction (AO). Severe AO is shown during both spontaneous ventilation (Spont) and mechanical ventilation (Mech V). TLC = total lung capacity. Functional residual capacity (FRC) is the static lung volume at the end of expiratory flow (60–90 seconds in severe AO). Expiratory reserve capacity (ER Cap) is the additional gas that expired with expiratory effort after FRC has been reached. Residual volume (RV) is the minimum lung volume possible after prolonged expiration and maximum expiratory effort. V_{trap} is the gas trapped by dynamic hyperinflation during tidal ventilation.

Non-Invasive Ventilation

Non-invasive ventilation (NIV) has been widely used for a variety of respiratory problems. In severe asthma, there are a number of potential benefits. Externally applied PEEP may help overcome PEEP_i due to gas trapping and thus reduce the inspiratory threshold work of breathing. Augmentation of inspiration with NIV may further decrease the work of inspiration and increase tidal volume and minute ventilation. If tidal volume is increased with a shorter inspiratory time, then increased minute ventilation can occur without a proportional increase in dynamic hyperinflation. Both inspiratory augmentation and PEEP may facilitate airspace opening, thus reducing V/Q mismatch.[113, 114]

The role of NIV is well established in chronic obstructive pulmonary disease where a number of randomised trials have shown benefits in hypercapnic respiratory failure.[115, 116] There are no large randomised trials in acute asthma in either adults or children; however, there is increasing observational evidence of benefit from NIV for acute severe asthma indication in studies indicating benefit with regards to rates of mechanical ventilation and mortality[117-119] and other outcome variables such as rate of improvement,[119, 120] decreased hospitalisation[119, 120] and reduced length of stay.[120]

Meta-analyses and consensus guidelines[121-122] and reviews of NIV for acute severe asthma[121, 123-126] have concluded that there is limited evidence for some benefits, but insufficient data to allow specific recommendations. Where opinions were given, all recommended use of NIV in selected patients with asthma.[123-126] Indications for use are (1) moderate to severe dyspnoea or respiratory distress, (2) hypercapnic acidosis and (3) respiratory rate >25, accessory muscle use or paradoxical breathing. Contraindications to NIV include cardiac or respiratory arrest, a decreased conscious state, severe upper gastrointestinal bleeding, haemodynamic instability, facial trauma or surgery, inability to protect the airway and clear secretions and high risk of aspiration.

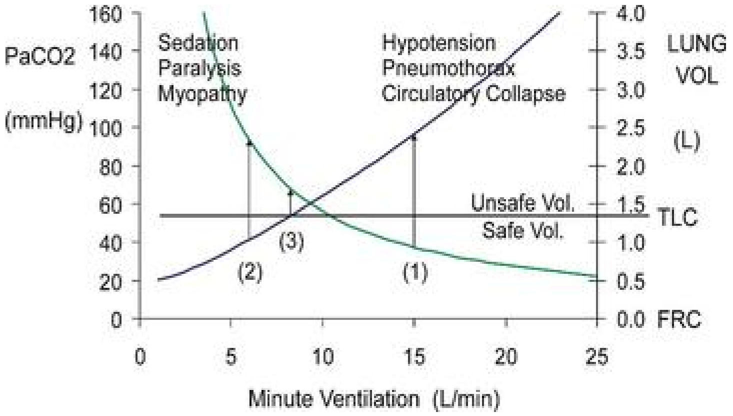
Nasal masks are usually not suitable in acute respiratory failure and facemasks or full-face masks fitted to achieve comfort and a reliable seal are usually best.

NIV should be commenced with 5 cm H_2O CPAP (expiratory positive airway pressure, EPAP 5 cm H_2O) and 8–10 cm H_2O pressure support (inspiratory positive airway pressure IPAP 13–15 cm H_2O). The aim is a respiratory rate of <25 breaths/minute and an exhaled tidal volume of 7 mL/kg. CPAP may be increased to 7 or 10 cm H_2O if there is difficulty initiating inspiration, or pressure support may be increased if tidal volume is low or respiratory rate remains high. It is not possible to reliably achieve total pressures (IPAP) >20 cm H_2O. NIV should be undertaken in an area familiar with its use and where close observation is available.

Complications of NIV include nasal bridge ulceration, mask discomfort, nasal congestion, gastric insufflation, aspiration, hypotension and pneumothorax.[112] However, hypotension and pneumothorax are uncommon compared with their risk during invasive mechanical ventilation.

Invasive Ventilation

Invasive mechanical ventilation in acute severe asthma may be life saving, but can be associated with significant morbidity and mortality[111] (Fig. 46.6). Institution of invasive ventilation with endotracheal intubation carries the risk of inadvertent pulmonary hyperinflation[107, 108, 111] and potential aggravation of bronchospasm and a significant part of the morbidity and mortality has been attributed to pulmonary hyperinflation.[107, 108, 111] Despite these risks, the incidence of mechanical ventilation for asthma is decreasing and mortality of patients ventilated for asthma is also decreasing in some series[8, 9] and decreasing in Australia & New Zealand (see Figs. 46.1 and 46.2 in this chapter).



The graph displays two intersecting curves against minute ventilation on the horizontal axis, with arterial partial pressure of carbon dioxide on the left vertical axis and lung volume on the right vertical axis. The curve slopes downward, showing a decrease in carbon dioxide pressure as ventilation increases, while the curve slopes upward, which indicates rising lung volume. Zones are marked as unsafe on the left and right, associated with sedation, paralysis, myopathy, hypotension, pneumothorax, and circulatory collapse. The middle zone is labelled safe volume. Horizontal lines mark total lung capacity and functional residual capacity on the right axis.

FIG. 46.6 The effects of minute ventilation on $PaCO_2$ and end-inspiratory lung volume above FRC in a typical patient with severe asthma. (1) The minute ventilation required for normocapnia, (2) profound hypoventilation, (3) optimal hypoventilation.

The decision to intubate depends on both the clinical status of the patient and the natural history of the type of asthma present. Hyperacute asthma may present with marked hypercapnia ($PaCO_2$ >60 mm Hg (7.98 kPa)) due to mechanical limitations of ventilation as a result of dynamic hyperinflation. Such patients may not initially be fatigued and may respond rapidly to treatment, thereby avoiding mechanical ventilation. Acute severe asthma that has been progressing for days may have less hypercapnia but will often respond poorly to treatment. The PaCO$_2$ may rise despite maximal treatment owing to fatigue and the patient may require intubation at a lower PaCO$_2$. The general principle is to use NIV early but to avoid mechanical ventilation if safe to do so.

The decision to intubate is based primarily on the degree of respiratory distress as assessed by an experienced clinician and the patient themselves. A patient with a high PaCO$_2$ (e.g. >70 mm Hg (9.31 kPa)) who is dyspnoeic but not distressed and who may respond to full treatment over a few hours needs close observation but not immediate intubation. Patients are often able to tolerate hypercapnia without requiring invasive ventilation.[127] Absolute indications for intubation include cardiac or respiratory arrest, severe hypoxia or rapid deterioration of the conscious state.[22,66] Relative indications include deteriorating status despite treatment of a patient who complains of respiratory exhaustion.

Once the decision to intubate has been made, a safe option is to perform rapid sequence intubation using the orotracheal approach. As large as possible endotracheal tube should be used to reduce the work of breathing and to reduce the risk of tube occlusion by the tenacious secretions that often occur with asthma. Once the endotracheal tube is in place, slow hand ventilation (8–10 breaths/minute) should maintain oxygenation until the ventilator can be connected.

Initial Ventilator Settings

The principles of initial mechanical ventilation are to avoid excessive DHI[107,110-112,128] and to avoid excessive hypoventilation (Fig. 46.6) by commencing with minute ventilation <115 ml/kg/min (<8 L/min in a 70 kg patient) best achieved with a tidal volume of 5–7 mL/kg, a respiratory rate of 10–12 breaths/min and a short inspiratory time to ensure an expiratory time ≥4 seconds.[107,110-112,128] This degree of hypoventilation will usually result in hypercapnic acidosis and continued respiratory distress necessitating heavy sedation and sometimes requires 1–2 bolus doses of a neuromuscular-blocking agent.

The use of volume-controlled ventilation is most established for this ventilatory pattern. In volume control, a high inspiratory flow rate (70–100 L/min) is required to achieve a short inspiratory time. This will result in a high peak airway pressure (PIP), but this will lower DHI and P_{plat} and reduce barotrauma compared with lower inspiratory flow rates.[107,111] Pressure-controlled or assisted modes have been used[129] without adverse consequences. The theoretical advantage of a safe pressure limit in pressure modes is offset by the fact that equilibrium with the set safe pressure cannot be reached during the short inspiratory times required and thus either a higher pressure must be set or more than necessary hypoventilation may occur. It is not clear whether one mode is superior to the other.

If significant hypotension occurs this should be treated by reducing the respiratory rate (thereby reducing dynamic hyperinflation) and volume loading.

PEEP

The role of extrinsic PEEP during mechanical ventilation of the patient with severe asthma requires careful consideration. During spontaneous breathing, CPAP has been shown to facilitate the initiation of the next breath and reduce the work of breathing in many patients with severe airflow obstruction. However, during initial controlled ventilation when there is an excessive level of PEEPi and dynamic hyperinflation and work of breathing is not an issue, early work has shown that extrinsic PEEP will further increase lung volumes. As this conferred no benefit and risk of detriment it was recommended that extrinsic PEEP should not be used.[112] More recently some research has suggested that low-level PEEP may improve the distribution of ventilation (as does hyperinflation) and reduce $PaCO_2$[130] and one study[131] has found that extrinsic PEEP may paradoxically reduce hyperinflation in some patients ventilated with airflow obstruction. The uncertain benefit and unpredictable responses to PEEP in these latter studies continue to suggest that extrinsic PEEP should not be routinely used during controlled ventilation for severe airflow obstruction.[112]

Assessment of dynamic hyperinflation

Once mechanical ventilation has started, the degree of DHI should be assessed by measurement of *plateau airway pressure* (P_{plat}). This is the airway pressure after transient expiratory occlusion at the end of inspiration. This may be achieved by an end-inspiratory hold function on most current ventilators, which delays the commencement of the next breath (Fig. 46.7), or by applying a 0.5 s ‘plateau’, which does not delay the onset of the next breath. The latter should be applied for a single breath only as an application for several breaths in a row will decrease expiratory time and progressively increase DHI. This is the most easily measured estimate of average alveolar pressure at the end of inspiration and is directly proportional to the degree of hyperinflation and should be maintained at <25 cm H_2O.[107, 111]

The two ventilator screenshots display numerical values and waveform graphics representing respiratory parameters. In the top display, key values include pressure forty three, p H six point eight, positive end expiratory pressure one point one, inspiratory to expiratory ratio one to five point seven, tidal volume three hundred eighty four millilitres, and minute volume four point seven two litres. Below these values are waveforms for pressure, volume, and flow over time. The bottom screen has similar graphs with slightly different values, such as pressure forty three, p H seven point four, positive end expiratory pressure one point zero, inspiratory to expiratory ratio one to five point seven, tidal volume three hundred eighty three millilitres, and minute volume four point eight nine litres. The graphical waveforms remain consistent in style and layout, reflecting synchronised respiratory patterns.

FIG. 46.7 **(A) The ventilator circuit pressure and flow traces versus time during controlled ventilation of a patient with severe airflow obstruction. Note the use of a low rate, low V_t, a high inspiratory flow rate (V_i 80 L/min) and hence a short inspiratory time (t_e < 1 second). This causes a high peak airway pressure but allows a long expiratory time (>4 seconds). Expiratory flow is low throughout expiration and appears close to baseline at the onset of the next breath (2nd on screen). Suggesting minimal gas trapping but when a PEEP$_i$ manoeuvre is done (end-expiratory pause) there is a surprising degree of PEEP$_i$ present (7.6 cm H_2O).** (B) The ventilator circuit pressure and flow traces versus time during controlled ventilation of the same patient in part (A). When a P_{plat} manoeuvre is done (end-inspiratory pause) the P_{plat} is safe (20 cm H_2O) with this ventilator pattern despite the degree of PEEP$_i$ present. Note the low P_{plat} despite the high peak airway pressure.

In patients with severe asthma, P_{plat} of 25 cm H_2O correlated with an average end-inspiratory lung volume of <20 mL/kg (1.4 L in a 70 kg patient, Figs. 46.4 and 46.5) above FRC. This has been shown to be a good predictor of complications during mechanical ventilation[111] and to correlate with a total lung volume at TLC.[110]

Intrinsic PEEP (PEEP$_i$) is the airway pressure during the occlusion of expiratory flow at the end of expiration (Fig. 34.5B). This is also an automated end-inspiratory hold function on most current ventilators. However, this measurement is known to underestimate true PEEP$_i$, as a consequence of small-airway closure during expiration resulting in many higher-pressure alveoli not communicating with the central airway at the end of expiration.[109] Because of this, PEEP$_i$ can be used to show the presence of DHI but is not recommended to regulate the level of mechanical ventilation.

Careful observation of the expiratory flow time curve can be valuable (Fig. 46.7). This is characteristically a deep concave curve with persistence of flow until the end of the expiratory period. The level of end-expiratory flow is not a reliable guide to the degree of hyperinflation as it depends on the expiratory time and lower expiratory flows, suggesting less gas trapping can have higher levels of PEEP$_i$. A valuable measurement of the severity of airflow obstruction is the percentage of Vt expired in the first second (see Chapter 39).

If the patient is haemodynamically unstable, an assessment of the change in blood pressure and central venous pressure should be made during a period of transient ventilator disconnection (1–2 min) or transient ventilator rate reduction (4–6 breaths/min for 2–4 min). If DHI has been suppressing circulation, then a significant increase in blood pressure and reduction in central venous pressure will occur.

Adjustment of Ventilation

Ventilatory patterns with excessive minute ventilation risk hypotension and barotrauma and are associated with high mortality. Use of profound hypoventilation will guarantee avoidance of these complications but usually necessitates heavy sedation and neuromuscular blockade (Fig. 46.6). This, in association with parenteral steroids, has a high probability of myopathy,[79, 132, 133] which may cause severe prolonged disability. To minimise the risk of both these complications, DHI should be carefully assessed and the minimum amount of hypoventilation used to achieve a safe level of DHI (see Fig. 46.6) in association with less sedation and minimal or no use of neuromuscular-blocking agents.

Ventilation should be adjusted based on an assessment of DHI, not on $PaCO_2$ *or pH.* If P_{plat} is >25 cm H_2O or circulatory suppression is present, the ventilator rate should be reduced.[107,134] If P_{plat} is low, ventilation can be liberalised by increasing the ventilator rate or reducing sedation and allowing spontaneous ventilation. Hypercapnia is usually present but is well tolerated[135] and does not appear to depress cardiac function. There is no evidence of benefit from sodium bicarbonate, but it may reduce acidaemia-induced respiratory distress and may be given if the pH is less than 7.1.

When airflow obstruction improves (decreasing P_{plat} and PEEP$_i$), sedation may be decreased, ventilator rate reduced and spontaneous ventilation assisted with pressure support ventilation. Pressure support of 10–16 cmH$_2$O may be used. Once spontaneous ventilation has commenced and when DHI is no longer critical, 3–7 cm H$_2$O CPAP may be introduced to assist ventilator triggering and reduce the work of breathing.

Complications of Invasive Ventilation in Asthma

Hypotension may be caused by sedation, DHI, pneumothoraces or arrhythmias.[107,111] Hypovolaemia may be a contributory factor but is rarely a cause. Hypotension may be mild or life threatening.[136] Hypotension due to DHI may be diagnosed by recovery of blood pressure during apnoea of 60 seconds (the ‘apnoea test’)[136] or by a longer period of low ventilator rate (4–6 breaths/min for 2–4 min). If this occurs, ventilation should be continued at a lower rate.

Circulatory arrest with pulseless electrical activity (PEA) is a recognised complication that may occur within 10 minutes of intubation and can lead to death or severe cerebral ischaemic injury if not managed correctly.[136-138] Standard mechanical ventilation recommendations (minute ventilation 115 mL/kg/min) have been estimated to be safe for 80% of patients requiring mechanical ventilation for acute severe asthma, with the remaining 20% requiring a small to moderate reduction in minute ventilation to return DHI to a safe level.[111] A small percentage of patients with unusually severe asthma can rapidly develop excessive DHI during initial uncontrolled mechanical ventilation leading to EMD, sometimes despite ‘safe’ levels of minute ventilation. If the cause of this is not immediately recognised, it can lead to prolonged and unnecessary CPR, unsafe procedures such as intercostal vascular access needles or pericardial taps and risk of cerebral injury and death. [136-138] When this occurs, immediate disconnection from ventilation for 60–90 seconds (the ‘apnoea test’, above) or profound hypoventilation (2–3 breaths/min) [66] will diagnose and improve this situation. An even smaller percentage of patients may remain hypotensive despite profound hypoventilation with marked hypercapnia, fluid loading and inotropes. These patients may require extracorporeal membrane oxygenation. [138-141]

Pneumothoraces were common before the advent of protective ventilatory strategies. DHI during mechanical ventilation was probably the major causative factor involved. [107], [111] Pneumothoraces may also occur as a consequence of intercostal needle insertion for suspected tension pneumothorax (not initially present) during circulatory arrest (above). Asthma continues to remain one of the three most common conditions (with ARDS and interstitial lung disease) associated with barotrauma during mechanical ventilation with a risk rate of 6.3% compared with an overall risk rate of 2.9% for all mechanically ventilated patients. [142] The presence of severe airflow obstruction prevents lung collapse and favours gas loss through the ruptured alveoli, with the result that tension is almost always present in the pneumothorax. Once a unilateral tension pneumothorax is present, this will necessarily reduce ventilation to that lung and redistribute ventilation to the contralateral lung thereby further increasing DHI in the second lung and bilateral tension pneumothoraces may result in severe adverse consequences.

As soon as a tension pneumothorax is suspected, the ventilator rate should be immediately reduced to decrease the risk to the second lung. Clinical diagnosis of a tension pneumothorax can be difficult as the lungs in severe asthma are already overexpanded and hyper-resonant with poor air entry. An urgent chest X-ray is always advisable for confirmation prior to intercostal catheter insertion unless severe hypotension is present. Intercostal catheters should always be inserted by blunt dissection. If intercostal needles are inserted for suspected pneumothorax, an intercostal catheter should always be inserted soon thereafter because if tension pneumothorax is not present it is highly likely after the intercostal needle.

Acute necrotising myopathy is a serious complication that may occur in patients who are invasively ventilated for asthma and receive neuromuscular-blocking agents or very deep sedation.[79, 132, 133, 143, 144] It is characterised by weakness with electromyographic evidence of myopathy and increased serum creatine kinase levels. Muscle biopsy reveals two patterns: myonecrosis with muscle cell vacuolisation or predominant type II fibre atrophy.[79, 143] Recovery can be slow with prolonged weaning from mechanical ventilation, and the need for rehabilitation. Incomplete recovery after 12 months has been reported in a few patients.[144, 145] The aetiology of the myopathy appears to be a combination of the effects of corticosteroids and neuromuscular-blocking agents (NMBA) with the duration of paralysis a strong predictor of myopathy.[144, 145] The type of NMBA used seems to make no difference to the incidence of myopathy.[143] Effective paralysis by deep sedation without the use of NMBAs also confers the risk of severe weakness in this patient group.[145] Gehlbach et al.[14] found that the risk factors for prolonged mechanical ventilation were female gender, use of NMBAs, requirement for inhaled corticosteroids prior to admission and a high illness severity score (APACHE II). The relative contributions of corticosteroids versus NMBAs in the causation of myopathy are unclear. It seems wise to minimise the dose of parenteral corticosteroids with the early introduction of nebulised agents, to minimise or avoid NMBAs if possible and minimise deep sedation.

Mortality, Long-Term Outcome and Follow-Up

Prior to the year 2000,[67] there was a high overall mortality of 12.4% for patients requiring mechanical ventilation for asthma with a progressive reduction in reported mortality during that period (see Fig. 46.2). A selection of international reports[8, 11, 13, 14, 30] published since 2000 have shown continued reduction in overall mortality (see Fig 46.2) but with mortalities as high as 21% still occurring in one series.[13] The largest and most comprehensive recent series comes directly from the Australian and

New Zealand Bi-National intensive care database over a 23-year period (2000–2023, Fig. 46.2). This series shows a decreasing requirement for mechanical ventilation for patients admitted to intensive care with severe asthma (Fig. 46.1) and a progressive reduction in annual mortality of the ventilated patients from 10% in the year 2000 to 2.9% in the period 2000–2023 (Fig. 46.2).

The need for invasive ventilation increases the risk of death[8, 13] and survivors of these near-fatal episodes of asthma have an increased risk of intensive care re-admission and an increased risk of death after hospital discharge.[44, 146] For these reasons, patients who have an episode of asthma severe enough to require hospitalisation, particularly intensive care admission, need careful follow-up. This should include active identification and avoidance of precipitants, aggressive bronchodilator therapy including inhaled steroids, regular medical review, regular measurement of lung function, management plans for a deteriorating status and ready access to emergency services.[147] Patients with difficult asthma may benefit from systemic assessment of factors contributing to their poor asthma control including detailed psychological and sometimes speech therapy assessment.[23] Those with severe asthma and evidence of eosinophilic (sputum or blood eosinophilia, elevated exhaled nitric oxide) or allergic (elevated total and specific IgE) inflammation may benefit from monoclonal biologics that target these pathways directly and have been shown to reduce exacerbations and improve symptoms, lung function and quality of life.[101]

Key points

1. Asthma prevalence in the community is increasing but admissions to hospital and intensive care are decreasing.
2. Acute severe asthma is a life-threatening medical emergency both on presentation and during mechanical ventilation.
3. Underestimation of severity and under-treatment are the biggest contributors to asthma mortality.
4. Patients who do require mechanical ventilation have more severe asthma refractory to treatment and are more difficult to ventilate.

5. Intravenous and continuous nebulised salbutamol can cause significant lactic acidosis.
6. Mechanical ventilation can easily cause excessive dynamic hyperinflation leading to hypotension and pneumothorax.
7. Mechanical ventilation needs careful regulation with initial $V_e <$ 115 mL/kg/min (8 L/min) and $P_{plat} <$ 25 mm Hg (3.32 kPa).
8. Very severe dynamic hyperinflation can lead to cardio-respiratory collapse diagnosed by an apnoea test.
9. Neuromuscular-blocking agents and heavy sedation can lead to severe necrotising myopathy.
10. Following intensive care, asthma requires full treatment including inhaled steroids, a management plan and careful follow-up.

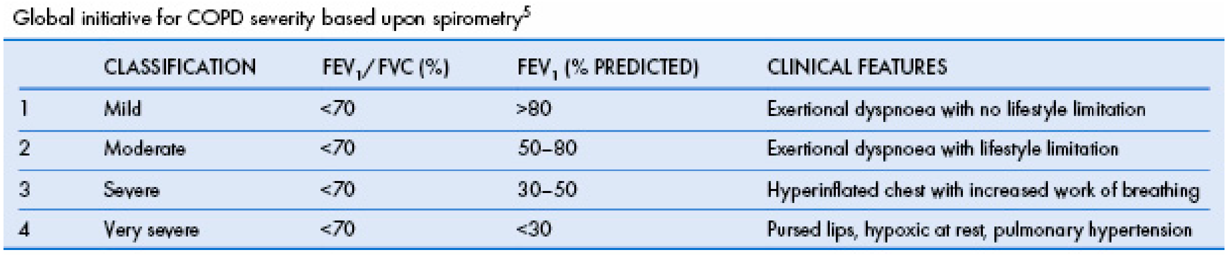
Acute respiratory failure in chronic obstructive pulmonary disease

Matthew T. Naughton and David V. Tuxen

The term chronic obstructive pulmonary disease (COPD) is applied to patients with chronic bronchitis and/or emphysema. COPD affects up to 10% of the adult population aged greater than 40 years and is the fourth most common cause of death worldwide.[1] COPD is increasing in prevalence, particularly in women.[2] COPD is commonly associated with cardiovascular disease, depression, gastro-oesophageal reflux, osteoporosis and cancer.[3,4] Severity of COPD can be easily assessed objectively by spirometry[5] (Table 47.1), radiologically with a CT scan of the chest and functionally based upon dyspnoea, exercise capacity and functional status (Table 47.2).[6]

Table 47.1



Global initiative for COPD severity based upon spirometry[5]

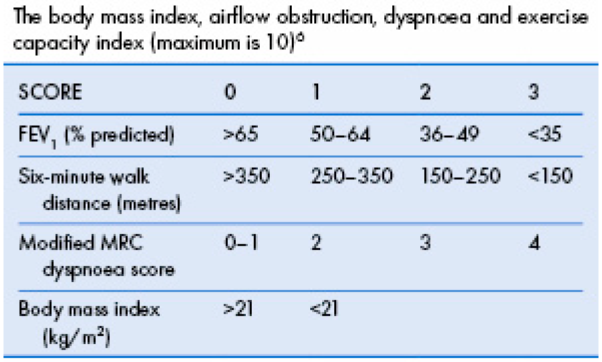
	CLASSIFICATION	FEV_1/FVC (%)	FEV_1 (% PREDICTED)	CLINICAL FEATURES
1	Mild	<70	>80	Exertional dyspnoea with no lifestyle limitation
2	Moderate	<70	50–80	Exertional dyspnoea with lifestyle limitation
3	Severe	<70	30–50	Hyperinflated chest with increased work of breathing
4	Very severe	<70	<30	Pursed lips, hypoxic at rest, pulmonary hypertension

---

FEV_1 , Forced expiratory volume in 1 second; *FVC* , forced vital capacity.

From Pauwels RA, Buist AS, Calverley PM, et al. Global strategy for the diagnosis, management, and prevention of chronic obstructive pulmonary disease. NHLBI/WHO Global Initiative for Chronic Obstructive Lung Disease (GOLD) Workshop summary. *Am J Respir Crit Care Med* . 2001;163(5):1256–1276.

Table 47.2



The body mass index, airflow obstruction, dyspnoea and exercise capacity index (maximum is 10)[a]

SCORE	0	1	2	3
FEV_1 (% predicted)	>65	50–64	36–49	<35
Six-minute walk distance (metres)	>350	250–350	150–250	<150
Modified MRC dyspnoea score	0–1	2	3	4
Body mass index (kg/m^2)	>21	<21		

The 4-year survival rates are 80% for a score of 2, 70% for 3–4, 60% for 5–6 and 20% for scores 7–10. Modified Medical Research Council (MRC) score is from zero (no dyspnoea) to 4 (extreme dyspnoea upon getting dressed or leaving the house).

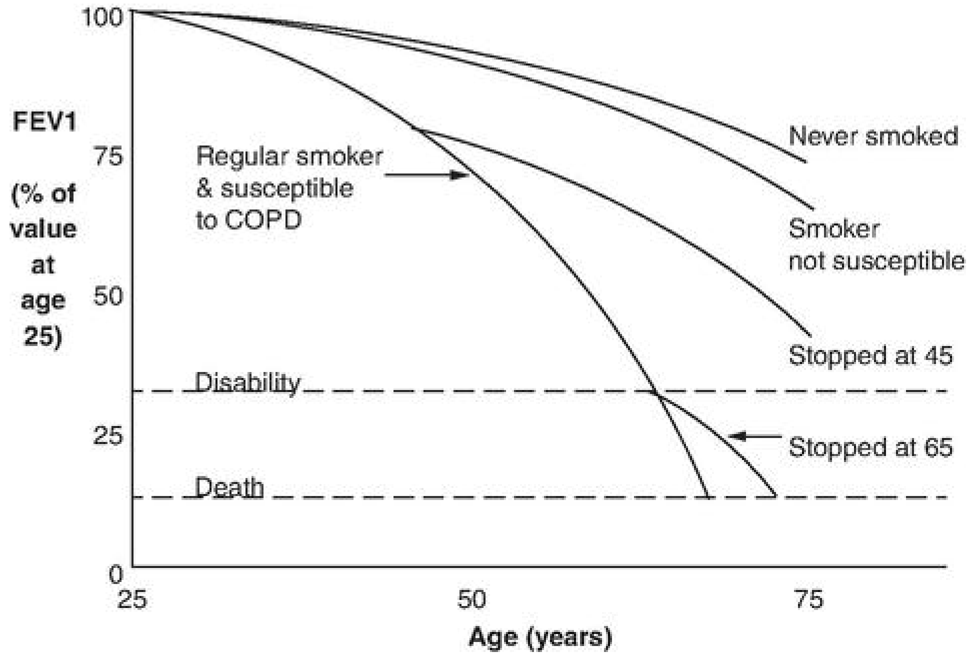
FEV_1, Forced expiratory volume in 1 second.

From Celli BR, Cote CG, Marin JM, et al. The body-mass index, airflow obstruction, dyspnea, and exercise capacity index in chronic obstructive pulmonary disease. *N Engl J Med*. 2004;350(10):1005–1012.

An acute exacerbation of COPD (AECOPD) is defined as 'an event in the natural course of the disease characterised by a change in dyspnoea, cough or sputum'.[4] AECOPD is the most common admission diagnosis in UK general hospitals (~16% of admissions).[4] Patients with an AECOPD have an in-hospital mortality of 3–8%, a 30-day re-admission rate of 23% and a 30-day mortality of 14%–26% (compared with 8% for myocardial infarction).[4, 7–9] Targeted oxygen therapy and non-invasive ventilatory (NIV) support have been the major advances in therapy in the past decade which have resulted in a reduced need for invasive mechanical ventilation (IMV) and improved survival. The need for either IMV or NIV ventilatory support in AECOPD varies considerably across continents; for example in the United Kingdom, NIV and IMV are used in 11% and 1% of admissions, respectively,[8] whereas in the United States, they are used in 5% and 3% of admissions, respectively.[9]

Aetiology

The causes of COPD can be divided into environmental and host factors. Environmental factors include tobacco smoke, air pollution, indoor fumes (e.g. indoor cooking with solid biomass fuel) and poor socioeconomic status. The biggest single factor in over 95% of patients with COPD is tobacco smoking. However, only approximately 15% of smokers develop COPD. Marijuana smoking may cause premature and quite advanced bullous emphysema compared with tobacco smokers due to extremely hot and toxic inhaled smoke held at peak inspiration for prolonged periods of time.[3] Host factors are the balance between circulating proteases and antiproteases (e.g. alpha-1 antitrypsin deficiency), neonatal history (low birth weight and prematurity) and the intake of antioxidant vitamins (A, C, E) (Fig. 47.1).[10]



The graph shows the percentage of forced expiratory volume at age 25 for different smoking habits from ages 25 to 75. The vertical axis ranges from 0 to 100 percent with markers at 25, 50, 75, and 100. The horizontal axis spans ages 25 to 75 with markers at 25, 50, and 75. Five lines track the decline. The first line represents never smoked, which remains the highest. The second line tracks regular smokers susceptible to chronic obstructive pulmonary disease with the steepest drop. The third line follows smokers not susceptible with a moderate drop. The fourth line shows those who stopped at 45 with a slower decline after quitting. The fifth line indicates those who stopped at 65 with an improved decline rate after quitting. Two dashed lines mark approximately 30 percent for disability and approximately 15 percent for death.

FIG. 47.1 Decline in lung function with age in different smoking categories. *COPD* , Chronic obstructive pulmonary disease [11] ; *FEV_1* , forced expiratory volume in 1 second.

Pathophysiology

Reduced expiratory airflow in COPD is due to both increased airway resistance and reduced lung elastic recoil. Airway resistance is increased by mucosal oedema and hypertrophy, secretions, bronchospasm, airway tortuosity, airflow turbulence and loss of lung parenchymal elastic tissues that normally support the small airways. Loss of lung elastic recoil pressure is due to both loss of lung elastin and loss of alveolar surface tension from alveolar wall destruction.

Reduced lung elastic recoil decreases expiratory airflow by reducing the alveolar pressure driving expiratory airflow and by reducing the intraluminal airway pressure, which normally distends small airways during expiration. Forced expiration increases alveolar driving pressure but also causes dynamic airway compression, resulting in no improvement or sometimes reduction in expiratory airflow. These factors are present in varying proportions, depending on the degree of chronic bronchitis and emphysema and the individual patient.

Airflow limitation results in prolonged expiration, pulmonary hyperinflation, inspiratory muscle disadvantage, increased work of breathing and the sensation of dyspnoea. All these factors are worsened during an exacerbation of COPD.

Pulmonary hyperinflation has both static and dynamic components. The static component remains at the end of an expiratory period long enough for all expiratory airflow to cease (30–120 seconds), enabling the lungs and chest wall to reach their static functional residual capacity (FRC). This component of hyperinflation is due to loss of parenchymal elastic recoil, chest wall adaptation and airway closure that occurs throughout expiration.[12] Dynamic pulmonary hyperinflation is the further increase in hyperinflation due to slow expiratory airflow not allowing completion of expiration before the arrival of the next breath. The extent of dynamic hyperinflation depends on the severity of airflow obstruction, the amount inspired (tidal volume) and the expiratory time.[13] Chest wall hyperinflation leads to suboptimal muscle length-tension relationships and mechanical disadvantage, thereby predisposing patients to respiratory muscle fatigue as the work of breathing increases, particularly if associated with myopathic situations (steroids, electrolyte disturbances).[14,15] Minor reductions in lung function due to infection, mild cardiac failure or atelectasis increase the work of breathing due to both increases in respiratory impedance and increases in dead space. With acute changes in workload, rapid decompensation with ventilatory failure and acute hypercapnia may occur.

Although chronic hypercapnia, as a consequence of reducing minute ventilation, is a fatigue-sparing mechanism that occurs in some patients, this is usually accompanied by renal compensation with retention of bicarbonate ions to correct the low pH caused by hypercapnic acidosis. Central respiratory drive may also be impaired, or poorly responsive to physiological triggers, hypoxaemia or hypercapnia and leads to chronic hypercapnia. This may occur in the setting of sleep (i.e. obstructive sleep apnoea),[12] obesity or drugs (sedatives, antiepileptics, alcohol).

Hypoxia and vascular wall changes lead to pulmonary vasoconstriction, pulmonary hypertension, cor pulmonale, V/Q mismatching and the development of shunts.

Chronic Bronchitis or Emphysema?

The value of labelling patients as chronic bronchitis or emphysema is uncertain as the two disease processes usually co-exist and the principles of management are similar. Five pathophysiological processes may be present to varying degrees in each patient with COPD: (1) inflammatory airway narrowing (bronchiolitis); (2) loss of connective tissues tethering airways; (3) loss of alveoli and capillaries; (4) hyperinflation; and (5) increased pulmonary vascular resistance. Early/mild COPD tends to be dominated by bronchiolitis with a minimal component of emphysema, whereas when COPD becomes severe, the reverse is true. However, recognition that COPD is dominated by one of these patterns is helpful with regard to clinical patterns and prognosis.

The precipitant of acute deterioration of COPD is infective (~50%), heart failure (~25%) and retained secretions, air pollution, co-existent medical problems (e.g. aspiration, pulmonary embolus, medication compliance or side effects), social issues or no cause can be identified in ~25% (Box 47.1).[15], [16]

Box 47.1

Precipitants of acute respiratory failure in chronic obstructive pulmonary disease

Infective (including aspiration)
Left ventricular failure (systolic and diastolic failure)
Sputum retention (postoperative, traumatic)
Pulmonary embolism
Pneumothoraces and bullae
Uncontrolled oxygen
Sedation
Medication – non-compliance or side effects
Nutritional (K, PO_4, Mg deficiency, CHO excess)
Sleep apnoea

Infection

The most common bacterial isolates are *Streptococcus pneumoniae* and *Haemophilus influenzae* in 80% of exacerbations. *Streptococcus viridans* , *Moraxella* (previously *Branhamella*) *catarrhalis* , *Mycoplasma pneumoniae* and *Pseudomonas aeruginosa* may also be found. Viruses can be isolated in 20%–30% of exacerbations and include rhinovirus, influenza, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) and other coronaviruses, parainfluenza viruses and occasionally adenovirus and respiratory syncytial virus. Background microbiological agents are identified in 48% of stable COPD compared with 70% during an AECOPD.

[17], [18] Pneumonia has been estimated to account for 20% of presentations requiring mechanical ventilation. [4]

Heart Failure

Left ventricular (LV) systolic failure may result from co-existing ischaemic heart disease, fluid overload, tachyarrhythmias (e.g. atrial fibrillation) or biventricular failure secondary to cor pulmonale. LV diastolic failure occurs commonly and is precipitated by hypoxaemia, tachycardia and pericardial constraint due to intrinsic positive end-expiratory pressure (PEEPi) or right ventricular (RV) dilation. [12], [19], [20] Increased work of breathing related to COPD will also increase by up to 10-fold the amount of blood flow to the respiratory muscles, [21] thereby causing an increased demand upon the overall cardiac output. The components of RV and LV failure can be accurately distinguished by Doppler echocardiography. Pulmonary congestion can be difficult to diagnose because of the abnormal breath sounds and chest X-ray appearance which are commonly present in COPD. In a recent publication, 51% of patients with AECOPD had echocardiographic evidence of left heart failure (systolic 11%, diastolic 32%, systolic and diastolic 7%). [12] Radiological and echocardiographic studies have identified that the severity of emphysema on CT scanning correlated with LV end-diastolic volume, stroke volume and cardiac output [19] and the association between increasing severity of COPD and worsening cardiac function.

Uncontrolled Oxygen administration

This may precipitate acute hypercapnia in patients with more severe COPD due to: (1) shunting blood to low-V/Q lung units and increasing dead space; (2) loss of hypoxic drive; (3) dissociation of CO_2 from Hb molecules (Haldane effect); and (4) anxiolysis and reduction in tachypnoea. [22] Randomised controlled trials have indicated significant reductions in the need for IMV, hospital length of stay and mortality with targeted oxygen therapy (i.e. a specific SpO_2 range, usually 88%–92%) compared with uncontrolled oxygen therapy in ambulances,[22] emergency rooms[23] and hospital wards.[8]

Diagnosis and Assessment

Clinical examination may also identify associated medical conditions that might have precipitated the exacerbation such as crackles and bronchial breathing due to infection, crackles and cardiomegaly related to heart failure or mediastinal shift related to a pneumothorax. Acute respiratory failure (ARF) in COPD can present with two distinct clinical patterns (Table 47.3),[16] namely, relatively thin and normocapnic or obese and hypercapnic.

Table 47.3

Clinical differences between normocapnic and hypercapnic chronic obstructive pulmonary disease

NORMOCAPNIC ($PaCO_2$ 35–45 mm Hg)	**HYPERCAPNIC ($PaCO_2$ >45 mm Hg)**
Emphysema > chronic bronchitis	Chronic bronchitis > emphysema
Thin	Obese
Pursed-lip breathing	Central nervous system depression: consider the role of oxygen therapy
Accessory muscle use	Alcohol, sedatives, analgesics
Hyperinflated	Sleep-related hypoventilation
Right heart failure late	Right heart failure early

Basic investigations such as spirometry are very useful in confirming a clinical diagnosis and determining the severity of the disease. An FEV_1/VC ratio of less than 70% with an FEV_1 of 50%–80% predicted normal without a bronchodilator response usually indicates mild COPD. A significant bronchodilator response, which implies asthma, is regarded as a 12% or greater increase and 200 mL increase in either FEV_1 or vital capacity (VC). An FEV_1 30%–50% predicted normal indicates moderately severe COPD and FEV_1 less than 30% predicted normal indicates severe COPD.[5]

Flow-volume curves usually demonstrate reduced expiratory flow rates at various lung volumes and the characteristic concave expiratory flow pattern. Lung volumes show elevated total lung capacity, FRC and residual volume. Characteristically, the residual volume/total lung capacity ratio is greater than 40% in COPD and represents intrathoracic gas trapping. The total lung carbon monoxide (TLCO) uptake is a measurement of alveolar surface area and its reduction approximates the amount of emphysema present (usually <80% predicted normal).

A chest X-ray will commonly show hyperinflated lung fields, as suggested by >10 ribs visible posteriorly, six ribs visible anteriorly or large airspace anterior to heart (>1/3 of the length of the sternum), flattened diaphragms (best seen on lateral chest X-ray) and a paucity of lung markings. Pulmonary hypertension is manifest by enlarged proximal and attenuated distal vascular markings and by RV and atrial enlargement. Lung bullae may be evident.

A high-resolution CT scan of the chest (1–2 mm slices) can demonstrate characteristic appearance and regional distribution of emphysema. It can also assess any co-existent bronchiectasis, LV failure and pulmonary fibrosis. Such scans are less sensitive than standard chest CT scans (1 cm slice) for detecting pulmonary lesions (e.g. neoplasms). Nuclear ventilation-perfusion scans can also provide a characteristic appearance of COPD.

An electrocardiogram (ECG) is commonly normal but may show features of right atrial or RV hypertrophy and RV strain, including P pulmonale, right-axis deviation, dominant R-waves in V1–2, right bundle-branch block, ST depression and T-wave flattening or inversion in V1–3. The ECG may also show co-existent ischaemic heart disease, tachycardia and atrial fibrillation. Elevated B-type natriuretic peptide (BNP) levels may also assist in the diagnosis of heart failure.[24]

Differential Diagnosis

Asthma with fixed airway obstruction can masquerade as COPD. This is due to poorly controlled asthma with recurrent inflammation and airway remodelling. Signs that this might be the case include a history of childhood allergic asthma, maintained TLCO on lung function, minimal emphysema on chest CT scans and lack of COPD risk factors such as smoking.

Bronchiolitis obliterans is a condition which presents as a fixed airflow obstruction following a viral illness, inhalation of toxic fumes, following bone marrow or heart/lung transplantation or related to drugs (e.g. penicillamine). It generally begins as a cough some weeks after insult and insidious onset of dyspnoea. There is a broad spectrum of radiological appearances from normal to reticulonodular to diffuse nodular. Lung tissue biopsy reveals characteristic chronic bronchiolar inflammation appearance, and if granulation tissue extends into the alveoli, it is referred to as bronchiolitis obliterans or organising pneumonia. Removal of the offending agent and instigation of steroids are generally associated with a favourable prognosis. Fixed airflow obstruction on spirometry, normal DLCO and expiratory versus inspiratory CT scan with evidence of gas trapping can assist in the diagnosis.

Bronchiectasis is often associated with fixed mild-to-moderate airflow obstruction. A chronic productive cough (daily for 2 consecutive years) is characteristic. Clinical features such as clubbing, localised pulmonary crackles and a characteristic appearance on high-resolution CT, with dilated or plugged small airways at least twice the size of accompanying blood vessels, assist in the diagnosis.

Congestive heart failure (CHF) may be a differential diagnosis of COPD, or simply co-exist, as both disorders are common in smokers. [12] Orthopnoea and paroxysmal nocturnal dyspnoea are features which correlate with heart failure severity. A past history of myocardial ischaemia or atrial fibrillation should alert one to the possibility of heart failure. An echocardiogram and high-resolution CT (looking for a shift in interstitial oedema with changes in posture from supine to prone) [25] are sensitive markers of CHF.

Assessment of Respiratory Failure

An AECOPD is defined as ‘an event in the natural course of the disease characterised by a change in dyspnoea, cough or sputum’.[4]

Arterial blood gases are mandatory to assess hypoxaemia, hypercapnia and acid-base status. Chronic hypercapnia may be recognised by a bicarbonate level greater than 30 mmol/L and a base excess greater than 4 mmol/L indicating renal compensation. However, other causes of high serum bicarbonate need to be excluded (e.g. diuretic therapy, high-dose steroids or high-volume gastric fluid loss) or chronic hypercapnia may be incorrectly assumed and the severity of COPD overestimated. Renal compensation for chronic hypercapnia will increase the serum bicarbonate by approximately 4 mmol/L for each 10 mm Hg (1.33 kPa) of chronic $PaCO_2$ rise above 40 mm Hg (5.3 kPa), to return pH to the low-normal range. Irrespective of the COPD patient’s usual $PaCO_2$ level, an acute increase in $PaCO_2$ leads to a decreased arterial pH. This indicates that compensatory mechanisms are exhausted and there is an increased risk of respiratory collapse. The agreement between arterial and peripheral venous blood gases in terms of pH or $PaCO_2$ is extremely).[26] Thus the use of peripheral venous blood gases to assess respiratory failure should be used with great caution.

Management of Respiratory Failure

Non-Ventilatory Management

Targeted Oxygen Therapy

Oxygen given by low-flow intranasal cannulae or 24%–35% Venturi mask should be titrated to achieve a targeted saturation using pulse oximetry (SpO_2) of 88%–92%, as these levels should avoid significant increases in $PaCO_2$. Increases in $PaCO_2$ are most common in patients with initial $PaCO_2$ greater than 50 mm Hg (6.7 kPa) and pH less than 7.35.[27] For this reason, ABGs should be repeated 1 hour following initiation of oxygen therapy, as with NIV, to ensure an optimal direction of improvement in the underlying AECOPD. If the rise in $PaCO_2$ is excessive (>1.33 kPa), then the FIO_2 should be reduced, titrating SpO_2 to 2%–3% below the previous value and arterial blood gases should be repeated. If no $PaCO_2$ rise occurs with oxygen therapy, then a higher SpO_2 may be targeted with repeat ABG.

Inadequate reversal of hypoxaemia (e.g. SpO_2 <85%) is suggestive of an additional problem such as pneumonia, pulmonary oedema or embolus or a pneumothorax. Investigation of this should commence and a more effective O_2 delivery system (e.g. nasal high flow (NHF)) should be used (see Chapter 41). Although high FIO_2 should be avoided, reversal of hypoxaemia is important and O_2 should not be withheld in the presence of hypercapnia or withdrawn if it worsens.

Bronchodilators

Bronchodilators are routinely given in all acute exacerbations of COPD because a small reversible component of airflow obstruction is common, and bronchodilators improve mucociliary clearance of secretions. A large meta-analysis of 22 large randomised controlled trials of ambulatory COPD patients involving either anticholinergics and/or β2 agonists (short- and long-acting) over 3–60 months indicated that anticholinergics were more favourable than placebo in terms of acute exacerbations and hospitalisations.[3, 28] There were no favourable advantages with β2-agonists compared with placebo for acute exacerbations or hospitalisations, and placebo was better than β2-agonists in terms of mortality.[28] There is a cardiovascular risk if given in excessive doses.[29]

Nebulised β-agonists may cause tachycardia, tremor, mild reductions in potassium and $PaCO_2$ (due to pulmonary vasodilatation) and tachyphylaxis. Excessive β-agonists can cause lactic acidosis β-agonists (e.g. salbutamol, terbutaline or fenoterol) given 2–4-hourly should be used routinely in combination with ipratropium. Parenteral sympathomimetic agents are not recommended for routine use.

Anticholinergic agents, such as ipratropium bromide, have been shown to have a similar or greater bronchodilator action than β-agonists in COPD, and also to have fewer side effects and no tachyphylaxis. An ipratropium bromide nebule of 0.5 mg in 2 mL should be nebulised initially 2-hourly, then every 4–6 hours. Long-term use of ipratropium bromide has been shown to reduce the incidence of exacerbations [30] and is therefore recommended for chronic use in ambulatory COPD. Long-acting anticholinergics (e.g. tiotropium) offer the potential of once-daily dosing.

Steroids

In acute exacerbations of COPD, short-term steroids have been shown to improve airflow obstruction including those patients requiring mechanical ventilation for COPD. [31] However, they have not been shown to alter ICU admission (or re-admission) rate, hospital length of stay, time to next exacerbation or mortality. [4] Doses similar to those for acute asthma should be used. Methylprednisolone 0.5 mg/kg, given 6-hourly for 72 hours, was used in the study by Albert et al. demonstrating benefit in patients with an exacerbation of COPD. [32] Current guidelines recommend the equivalent to oral prednisolone at 0.5 mg/kg body weight for 5 days, [33] then ceasing; however, this will depend upon the response to treatment and their premorbid use.

Antimicrobials have an accepted role in the treatment of infection-induced exacerbations of COPD. Amoxicillin is a suitable first-line agent against *H. influenzae* and *Streptococcus pneumoniae* for outpatient exacerbations. [4] Serious exacerbations requiring hospital admission require newer agents such as ciprofloxacin or a third-generation cephalosporin. Antibiotics and antivirals for pneumonia are discussed in Chapter 48 .

Aminophylline

Aminophylline is a weak bronchodilator in COPD. It improves diaphragm contractility, stimulates respiratory drive, improves mucociliary transport and right heart function, is anti-inflammatory and is a weak diuretic. [34], [35] Some studies have shown no benefit and significant side effects, whereas others have shown small benefit [36] in stable COPD. For an exacerbation, a trial of aminophylline can be considered (loading dose 5–6 mg/kg IV over 30 min, followed by an infusion of 0.5 mg/kg per hour). Serum theophylline levels must be monitored regularly to reduce risk of toxicity.

Anticoagulants

Clexane 20–40 mg daily is recommended as a prophylactic measure against venous thromboembolism. There is no evidence to support warfarinisation or NOACs in COPD patients with pulmonary hypertension.

Electrolyte Correction

Electrolyte correction is important. Hypophosphataemia,[14] hypomagnesaemia,[37] hypocalcaemia[15] and hypokalaemia may impair respiratory muscle function. Hyponatraemia may occur with inappropriate antidiuretic hormone release or with excess use of diuretics and inappropriate intravenous fluids.

Nutrition

Nutrition is important, as patients with severe COPD are often undernourished; a subnormal body mass index (BMI) is a risk factor for mortality in COPD.[6] Excessive carbohydrate calories should be avoided, as this increases CO_2 production (by >15%) and may worsen respiratory failure. Low-carbohydrate/high-fat combinations are preferred in ARF during spontaneous ventilation.

Chest Physiotherapy

Encouragement of coughing and deep breathing are the two most important factors. ‘Bubble positive expiratory pressure (PEP)’ is an inexpensive method of assisting sputum clearance in spontaneously breathing patients with retained secretions or those having difficulty expectorating.

Nebulised Mucolytic Agents

Nebulised mucolytic agents, such as N acetylcysteine, have been shown to reduce cough frequency and severity in stable COPD[38] but have no proven role in acute exacerbations of COPD.

Nasal High-Flow Cannula

Oxygen therapy by high-flow nasal cannulae is now an accepted therapy in patients with acute hypoxaemic respiratory failure[39] or when weaning from

IMV.[40-44] This therapy will be discussed in Chapters 41 .

Clinically, NHF is useful in ARF without hypercapnia [39] and post extubation from IMV.[40] NHF is now commonly used prior to NIV in AECOPD patients with only mild-to-moderate respiratory distress and lower levels of hypercapnic acidosis.[45] This is known to be better tolerated and has been shown to be non-inferior to NIV.

Non-Invasive Ventilation

NIV is now a routine standard of care for AECOPD. When applied well, NIV has a similar physiological effect as IMV.[46] Two landmark randomised controlled trials in ICU [47] and in general medical wards [48] clearly indicated a role for NIV in hypercapnic AECOPD. Since then, there have been several randomised controlled trials and meta-analyses of NIV in hypercapnic AECOPD which have demonstrated improved respiratory physiology, reduced mortality (up to 12 months), reduced iatrogenic complications, reduced need for intubation and mechanical ventilation and reduced length of stay in hospital.[8], [9], [49], [50] All studies have shown good tolerance of the technique with few side effects and improvements in both oxygenation and $PaCO_2$ compared with medically treated control patients. Overall, NIV is associated with reduced intubation rate, hospital and intensive care length of stay plus mortality.[49], [50]

Two important reviews of acute NIV use in AECOPD from the United States and the United Kingdom have been recently published. In the United States between 1998 and 2008, the use of NIV increased (from 1.0% to 4.5% of all admissions) and IMV decreased (from 6.0% to 3.5%), with NIV eclipsing IMV in 2008.[9] Associated with this significant change in pattern of ventilatory support was an overall reduction in mortality in those started on NIV or IMV early.[9] In the United Kingdom, during a 3-month snapshot of 232 hospitals in 2008, 11% of all admissions with AECOPD received NIV.[8] Oxygen toxicity was found to occur in a third of hypercapnic AECOPD.[8] In both US and UK studies, NIV failure with transfer to IMV was associated with the greatest mortality (estimated to be ~30% [US]–40%

[UK]) compared with successfully used NIV (6% [US]–11% [UK]) and non-hypercapnic COPD (~3% [US], 5% [UK]).

The goal of NIV is: (1) to unload respiratory muscles and augment ventilation and oxygenation, reduce CO_2 and correct acidosis until the underlying problem can be reversed; (2) when applied intermittently, to offset the adverse effects of sleep or position-induced adverse changes to ventilation, increased upper-airway resistance and lung volume.

Indications for NIV are a deterioration of COPD with: (1) acute dyspnoea; (2) respiratory rate greater than 28 breaths/min; (3) $PaCO_2$ greater than 45 mm Hg (6 kPa) with a pH less than 7.35, despite optimal medical treatment and not related to excessive supplemental oxygen.[8,49,50] Although these indications are for mild exacerbations, most randomised trials have used these as eligibility criteria. Initial guidelines recommended NIV use be limited to patients with pH in the range of 7.25–7.35; however, recent evidence suggests that NIV is useful even in those patients with lower pH values (to as low as 7.0) and associated more severe hypercapnia (as high as 18 kPa).[51]

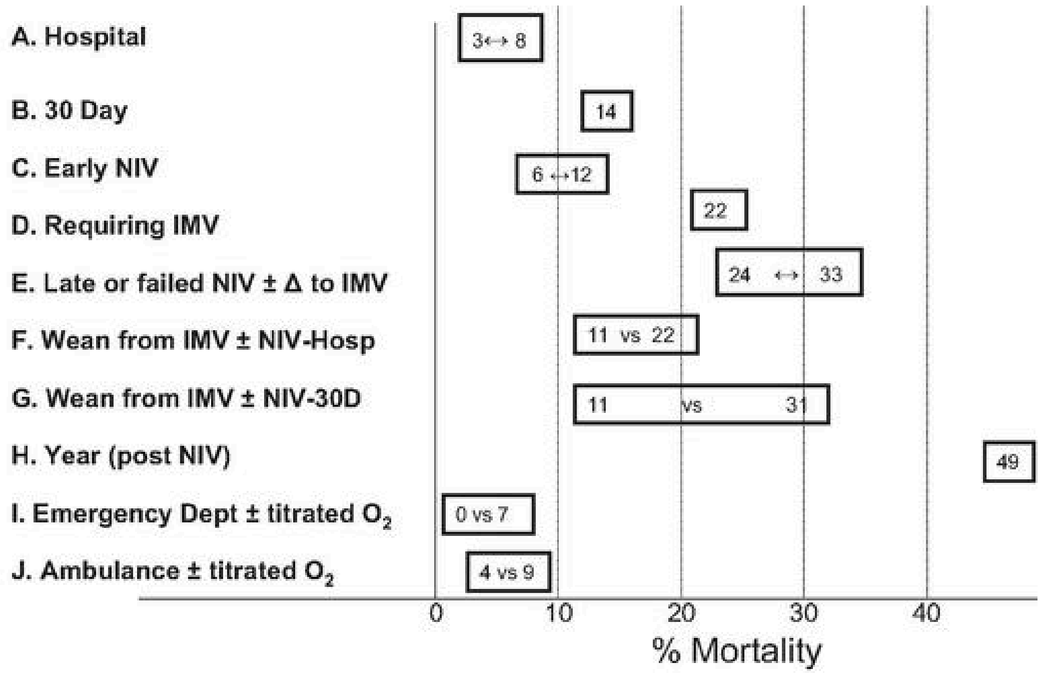
Included in the indications are recently extubated patients in whom NIV has been shown to reduce reintubation rates significantly.[52,53] Recently, NIV has been advocated for use in patients with hypoxaemic respiratory failure,[54] but success is significantly less in the setting of hypoxaemia and either normocapnia or hypocapnia. NIV may also have a role in some patients where mechanical ventilation is considered inappropriate.

Side effects of NIV include discomfort, intolerance, skin necrosis, gastric distension and aspiration. Pressure support has been reported as better tolerated than assist/control.[55] End-of-life plans should be considered in all patients with AECOPD, particularly those undergoing NIV, as ~20% of patients will fail to respond or deteriorate. This period of time on NIV can be used to assess resuscitation status.

Invasive Mechanical Ventilation

When respiratory failure progresses despite aggressive conservative management, including NIV, IMV may be necessary. The decision to ventilate requires careful consideration in some patients who may have near-end-stage lung disease and whose quality of life may not justify aggressive treatment. This decision requires consideration of the outcome of ARF.

An episode of ARF further decreases survival (Fig. 47.2). ARF precipitated only by bronchitis has a better outcome, whereas ARF due to more serious causes, such as pneumonia, LV failure and pulmonary embolus, has a worse outcome and studies including all such outcomes have lower survival rates.



The horizontal bar chart compares mortality percentages for two groups across 10 medical outcomes. The horizontal axis shows mortality from 0 to 40 percent with markers at 0, 10, 20, 30, and 40. The vertical axis lists categories A to J. Category A, hospital, shows 3 percent for the first group and 8 percent for the second. Category B, 30 day, shows 14 percent for both groups. Category C, early noninvasive ventilation, shows 6 percent for the first group and 12 percent for the second. Category D, requiring invasive mechanical ventilation, shows 22 percent for both groups. Category E, late or failed noninvasive ventilation leading to invasive mechanical ventilation, shows 24 percent for the first group and 33 percent for the second. Category F, wean from invasive mechanical ventilation with high flow nasal cannula oxygen, shows 11 percent for the first group and 22 percent for the second. Category G, wean from invasive mechanical ventilation with nasal cannula oxygen 30 D, shows 11 percent for first group and 31 for the second group. Category H, year post invasive mechanical ventilation, shows 49 percent for both groups. Category I, emergency department and titrated oxygen, shows 0 percent for the first group and 7 percent for the second. Category J, ambulance and titrated oxygen, shows 4 percent for the first group and 5 percent for the second. The chart highlights mortality differences in respiratory care outcomes.

FIG. 47.2 Estimated mortality for groups of patients with acute exacerbations of chronic obstructive pulmonary disease (AECOPD). A and B groups: refer to in-hospital and 30-day mortality [8], [9]; C group: refers to the early institution of non-invasive ventilatory (NIV) [8], [9]; D group: refers to patients requiring invasive mechanical ventilation (IMV) [9]; E group: refers to hypercapnic AECOPD patients either failing NIV and needing IMV, or those identified late as requiring NIV [8], [9]; F and G groups: weaned from IMV and randomised to either immediate NIV or not (i.e. randomised controlled trial) with in-hospital and 30-day mortality [52]; H group: 1-year mortality post NIV [7]; I and J groups: effect of titrated versus untitrated oxygen at emergency department [23] and ambulance. [22]

If ARF requires IMV, survival decreases further still (see Fig. 47.2). Although only 1% [8] –3.5% [9] of patients with AECOPD require IMV, and 4.5% [9] –11% [8] need NIV, the short-term survival in this more severe subset is still good, with a hospital survival rate in some series as high as 90%, but 2- and 3-year survival is significantly lower. The severity of ARF and the severity of underlying COPD based on FEV_1, lifestyle score and dyspnoea score are also predictors of outcome. Lifestyle and dyspnoea categories may be the most useful factors in the decision to withhold IMV. New Your Heart Association class 3 (house-bound and at least partly dependent) and 4 (bed-

or chair-bound) indicate both a poor outcome [56] and quality of life that may not justify aggressive treatment.

Thus IMV may be withheld in end-stage lung disease when low survival, poor quality of life or permanent ventilator dependence are likely. If end-stage lung disease is suspected but there is insufficient information, then a brief trial of aggressive therapy, including IMV, should be undertaken and subsequently withdrawn if unsuccessful. Despite this, most patients with COPD who present with ARF do not have end-stage disease and, although their immediate problems may be life threatening, their short-term outcome is sufficiently good to justify full active treatment.

Many studies have indicated that hospitals with high NIV use have a very low need for IMV to treat AECOPD. In the largest study to date, NIV use for AECOPD varied from 9% to 94% in the United States and was independent of the severity of COPD. [57] Moreover, the greater the NIV use, the less IMV was needed, with downstream benefits in terms of hospital length of stay, reduced costs and reduced mortality. Thus familiarity with NIV is hugely important to the successful caring of patients with AECOPD.

Invasive Mechanical Ventilation Technique

The goals of IMV in COPD are to support ventilation whilst reversible components improve, to allow respiratory muscle to rest and recover whilst preventing wasting from total inactivity and to minimise dynamic hyperinflation. For example low-level ventilatory pressure support, ie may be commenced on 8–15 cm H_2O pressure support, with 3–8 cm H_2O PEEP. Patients who are completely exhausted, post-arrest, comatose or not tolerating pressure support alone, should be commenced or transferred to synchronised intermittent mandatory ventilation mode.

Excessive dynamic hyperinflation [58-59] must be avoided by using low-minute ventilation – this strategy is explained in more detail in Chapter 46 (Acute Severe Asthma).

Most patients with AECOPD do not require controlled hypoventilation and can be managed with SIMV and continuous positive airway pressure (CPAP) pressure support. Spontaneous ventilation should be encouraged to promote ongoing respiratory muscle activity and to minimise skeletal muscle wasting. Flow-by, pressure support and low-level CPAP may all reduce the work of spontaneous breathing and promote a better ventilatory pattern. CPAP approximately equal to the level of PEEPi is most commonly recommended to make ventilator triggering easier.[60] Care must be taken with all of these supports, as each can increase dynamic hyperinflation by different mechanisms. Flow-by increases resistance through the expiratory valve, pressure support increases tidal volume and may increase inspiratory time and CPAP may increase lung volume.

Weaning From Invasive Mechanical Ventilation

Approximately 6%–20% of patients on IMV support fail ventilatory weaning.[52, 53] Numerous criteria have been proposed to assess the capacity of the patient to wean from mechanical ventilation[61, 4]; however, the predictive value of any of these individual criteria is limited. The simple criterion of patient respiration rate/tidal volume less than 100 breaths/min per litre had the best predictive value for weaning success, but the advantage of this overly simple clinical assessment during weaning is uncertain. Other indications to safely extubate COPD patients include an $FIO_2 < 40\%$; PaO_2 / FIO_2 ratio greater than 200 mm Hg (27kPa), PEEP 5 cm H_2O, cardiovascular stability, afebrile, pH greater than 7.35, $PaCO_2$ less than 50 mm Hg (6.7 kPa), if available to be measured, static compliance greater than 25 mL/cm H_2O.[52] Some patients unable to achieve these criteria may require ventilatory weaning with $PaCO_2$ 50–65 mm Hg (6.7–8.7 kPa) with a bicarbonate level of greater than 30 mmol/L allowed or encouraged to reduce the work of breathing and achieve a less abnormal pH. Following extubation, consideration for NHF or NIV. NIV in acute hypercapnic COPD is associated with reduced reintubation rates, lower ICU and hospital length of stay and mortality and morbidity.[52, 53] Synchronisation of long-term NIV, especially during sleep, is crucial and may require polysomnography.[62]

Tracheostomy

Tracheostomy may be beneficial in a small group of patients who have failed extubation despite NIV, or who have successfully weaned but are unable to adequately clear secretions, or who have required long-term ventilatory support. After 10–14 days of endotracheal intubation, the risk of laryngeal trauma and sepsis increases. In a patient with COPD who has been unable to extubate after this time period, a careful assessment of the patient's expected long-term outcome should be undertaken before performing a tracheostomy which may commit the patient to long-term in-hospital care.

A tracheostomy allows long-term ventilatory support, sputum clearance, protection of the upper airway from oral secretions and, off mechanical ventilation, reduced dead space and upper-airway resistance.

Consider removing the tracheostomy when:

1. the oxygenation requirement is low (e.g. FIO_2 <40%)
2. the patient does not require ventilatory support or requires only intermittent low-level ventilatory support and NIV support is available
3. the patient is cooperative and has a good capacity to cough and can, for example, clear secretions via the tracheostomy tube
4. the patient has a low suction frequency requirement (<2–4-hourly)

Before tracheostomy removal, a multidisciplinary team approach is recommended to ensure the patient is able to protect the upper airway from aspiration and can swallow safely and there is an absence of upper-airway obstruction (e.g. no granulation tissue or tracheal stenosis).

Extra-Corporeal Membrane Oxygenation (ECMO)

ECMO is not usually recommended or used for patients with COPD or with AECOPD. Patients who present with AECOPD, who require mechanical ventilation, usually have severe baseline COPD and if mechanical ventilation is inadequate their survival would be unlikely and ECMO inappropriate. A rare exception to that would be a patient with mild COPD but severe pneumonia where survival, recovery and return home was a reasonable possibility.[63] ECMO is not recommended as a bridge to transplant in patients with COPD.

Extra-Corporeal CO_2 Removal (ECCOR) has been postulated as an alternative to mechanical ventilation. There has been some promising early work[63] but this has not gained any widespread support or use for patients with AECOPD.

Post-Intensive Unit Care

Care Bundles

A systematic approach to the management of acute exacerbations of COPD summarised in ‘care bundles’, used at the time of admission and discharge, are associated with improved survival, greater NIV use, shorter length of stay and reduced re-admission rates.[64] Care bundles are a method of ensuring optimal care is provided uniformly across large organisations. Using ‘care bundles’ at the time of admission, attention is given to (1) obtaining a correct diagnosis, (2) targeted oxygen therapy, (3) recognition and management of respiratory acidosis (i.e. NIV), (4) correct treatment and (5) respiratory specialist review within 24 hours. At the time of discharge, ‘care bundles’ are directed towards ensuring (1) inhaler technique, (2) self-care management plans, (3) smoking, (4) pulmonary rehabilitation and (5) telephone contact within 72 hours post discharge.

Reassessment of Potential Precipitating Causes

COPD is commonly associated with cardiovascular disease, depression (and social isolation) and occult malignancy, all of which may need further management following admission. The following should be considered to prevent re-admission

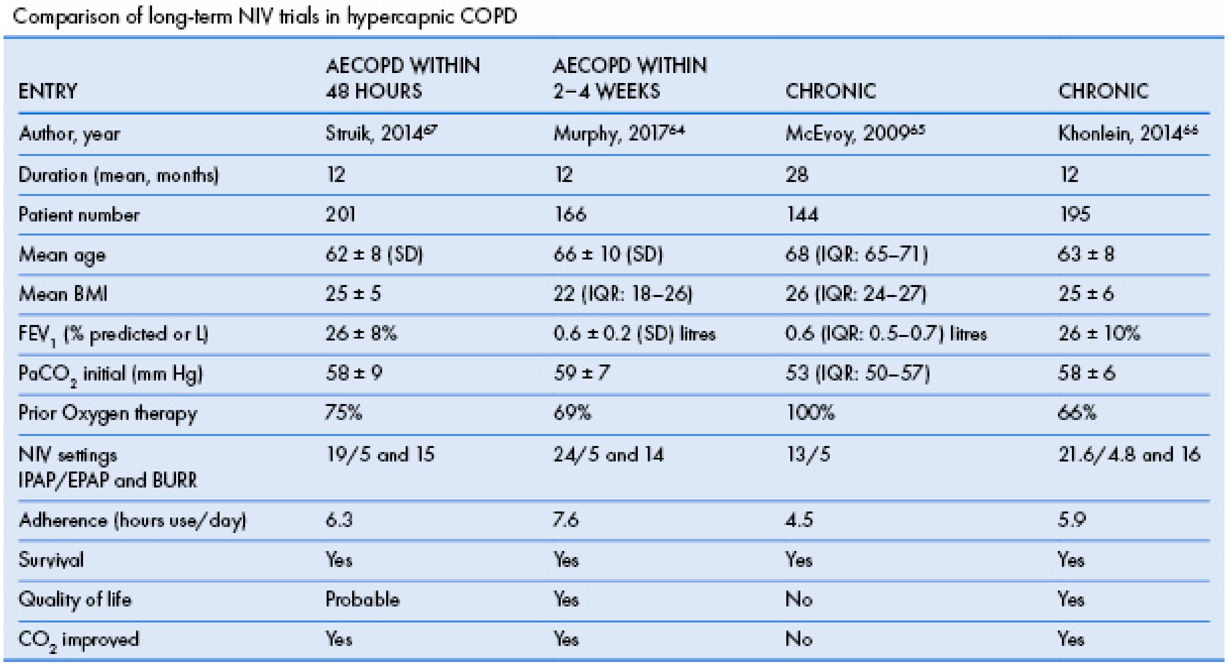
- Enrollment in a physical rehabilitation programme[70-71]
- Confirm diagnosis of COPD with lung function

- Exclude common co-existent disorders (heart failure and sleep apnoea[65])
- Ensure vaccination status is up to date
- Consider domiciliary
    - oxygen therapy[72,73]
    - NIV[66-69]

Consider surgical options (lung volume reduction and transplantation)[74]

Note in COPD patients with chronic hypercapnia, avoidance of excessive domiciliary oxygen therapy is advised.[8,22,23] Whether long-term domiciliary nocturnal NIV is required in this group is less clear. Four large and long-term studies (Table 47.4) have been conducted in which most,[66-68] but not all,[69] have indicated improved physiology (sleep quality and ABG) with an improvement in survival and re-admission rate.

Table 47.4



Comparison of long-term NIV trials in hypercapnic COPD

ENTRY	AECOPD WITHIN 48 HOURS	AECOPD WITHIN 2–4 WEEKS	CHRONIC	CHRONIC
Author, year	Struik, 2014[67]	Murphy, 2017[64]	McEvoy, 2009[65]	Khonlein, 2014[66]
Duration (mean, months)	12	12	28	12
Patient number	201	166	144	195
Mean age	62 ± 8 (SD)	66 ± 10 (SD)	68 (IQR: 65–71)	63 ± 8
Mean BMI	25 ± 5	22 (IQR: 18–26)	26 (IQR: 24–27)	25 ± 6
FEV_1 (% predicted or L)	26 ± 8%	0.6 ± 0.2 (SD) litres	0.6 (IQR: 0.5–0.7) litres	26 ± 10%
$PaCO_2$ initial (mm Hg)	58 ± 9	59 ± 7	53 (IQR: 50–57)	58 ± 6
Prior Oxygen therapy	75%	69%	100%	66%
NIV settings IPAP/EPAP and BURR	19/5 and 15	24/5 and 14	13/5	21.6/4.8 and 16
Adherence (hours use/day)	6.3	7.6	4.5	5.9
Survival	Yes	Yes	Yes	Yes
Quality of life	Probable	Yes	No	Yes
CO_2 improved	Yes	Yes	No	Yes

BURR , Backup respiratory rate; *EPAP* , expiratory positive airway pressure; *IPAP* , inspiratory positive airway pressure.

COPD Prognosis

Patients with sufficiently severe COPD to warrant hospital admission incur an inpatient mortality of 8%, and a 90-day mortality of 15% in the United Kindom. [8] , [9] Predictors of mortality were performance status, age and admission urea, albumin, pH, $PaCO_2$ and SpO_2 plus the presence of respiratory physicians involved in the care. [75] Although in-hospital mortality for hypercapnic COPD patients may reach 62%, [76] in an Australian report, in-hospital mortality for hypercapnic COPD patients treated with NIV was 11% and all deaths were with palliative intent, which followed time to allow for patient and family discussions. [51] In Hong Kong, acute hypercapnic COPD patients have a 12-month re-admission rate of 80% and a 49% 1-year mortality. [7] The BMI, airflow obstruction, dyspnoea and exercise capacity (BODE) index is a 10-point scale made up of the following four variables: (1) BMI, (2) airflow obstruction, (3) severity of dyspnoea and (4) exercise capacity, and has been found to be very useful in predicting survival in ambulatory patients with COPD (see Table 47.2).[6]

Interstitial Lung Disease

Such disorders are characterised clinically and radiologically.[77] Common clinical symptoms are tachypnea usually with hypoxaemia on exercise or at late stages at rest. Examination findings usually include pulmonary crepitations and occasionally digital clubbing. High-resolution CT chest scan appearances include honeycombing, traction bronchiectasis and/or air space consolidation. Lung biopsies are less commonly performed. Lung function tests indicate restriction (low FVC and total lung capacity) and gas exchange (low TLCO). When ILD is suspected or identified, a thorough history of occupational and other exposures, hobbies and associated medical conditions (including medications) is required.

Current recommendations for the diagnosis and management of ILD are via a multidisciplinary meeting (respiratory physician, radiologist and pathologist) to determine the type of ILD, therapeutic options and prognosis. For example, usual interstitial fibrosis (UIP), non-specific interstitial pneumonitis (NSIP), hypersensitivity pneumonitis (HP) and connective tissue disease-related ILD (CT-ILD) are commonly used categories of ILD. Importantly, differential diagnoses include lymphangitis carcinomatosis and drug reactions (e.g. amiodarone and methotrexate). Serial lung function and CT chest are useful for monitoring the progression of the disease. Current antifibrotic drugs (pirfenidone or nintedanib) and anti-inflammatories (prednisolone, mycophenylate, cyclophosphamide) may slow the progression of ILD. Lung transplantation should be considered early in the diagnosis and if deemed appropriate from medical and social aspects rapid referral to a lung transplant service.

A patient with ILD may be admitted to HDU or ICU at the time of diagnosis or later in the disease process as an incidental finding. Important aspects in such patients are to question the diagnosis and search for reversible causes (e.g. assess for pulmonary oedema and infection or pulmonary emboli) and set realistic goals of care. In the setting of progressive respiratory failure (usually hypoxic i.e. type 1) escalation from low-flow oxygen to high-flow humidified oxygen should be considered with the establishment of an appropriate SpO_2 target (often reduced to 85%–90%) noting that excessive oxygen can lead to lung fibrosis (known as the Lorraine Smith Effect).

Careful consideration about the stage of disease, goals of care and reversible components should be made before IMV is considered. Mechanical ventilation should only be initiated if there is a potentially reversible element. Fluid retention can be an aggravating factor not clearly identified by chest X-ray and a trial of diuresis to avoid mechanical ventilation may be valuable. A trial of high-dose steroids may be worthwhile if there is no other reversible cause and there may be an untreated inflammatory component. Lung protective ventilation ($P_{dr} < 14$ cm H_2O and $P_{plat} < 30$ cm H_2O) is very important as the lungs are usually very stiff and will only tolerate a low V_t . ECMO should only be considered if there is a clear bridge to lung transplantation within a short time frame.

Pneumonia

Wai Tat Wong, Eunise WS Ho and Lowell Ling

The key challenges and principles of management of pneumonia include:

- Pneumonia is associated with a wide range of largely non-specific clinical features.
- Pneumonia can be caused by over 100 pathogens.
- Clinical features alone are rarely sufficient to allow identification of the causative pathogen to guide initial antimicrobial therapy and early empirical treatment is recommended.[1,2]
- While appropriate antibiotics are essential for bacterial pathogens, specific treatments are not yet available for some pathogens such as viruses and supportive care is a key aspect of management.
- Confirmatory microbiology is often absent and assessment of response to empirical antimicrobial therapy is important.[3]

The diagnosis and treatment of pneumonia is often challenging. Choice of early empirical antimicrobial therapy should be guided by clinical history, local epidemiology of respiratory pathogens, antibiotic resistance burden, and severity of illness. Microbiological culture and tests should be taken to confirm the respiratory pathogen to facilitate the de-escalation of initial empirical broad antimicrobials. Complications of pneumonia and alternative differential diagnoses of non-infective causes of respiratory failure should be considered when clinical response to antimicrobial therapy is unsatisfactory.

Community-Acquired Pneumonia

Evidence-based guidelines have been issued by the UK National Institute for Health and Care Excellence (NICE), the British Thoracic Society (BTS), American Thoracic Society (ATS), European Respiratory Society (ERS), European Society of Intensive Care Medicine (ESICM), European Society of Clinical Microbiology and Infectious Diseases (ESCMID), and Latin American Thoracic Association (ALAT) for management of community-acquired pneumonia (CAP).[1, 4-6]

Definition

CAP is defined as an acute infection of the pulmonary parenchyma associated with systemic symptoms of acute infection or respiratory symptoms, accompanied by new infiltrates on radiological imaging or clinical findings consistent with pneumonia (e.g. altered breath sounds and localised crackles) in a patient not hospitalised prior to the onset of symptoms.

The overall incidence is 3–40 per 1000 inhabitants per year with 40%–60% requiring hospital admission.[4] Overall, 5%–10% of patients are admitted to ICU. The overall mortality of hospitalised patients is approximately 10%.[4, 7]

Aetiology

The epidemiology of causative pathogens has changed over time and is partly due to the availability of new molecular tests. Table 48.1 gives possible aetiological agents based on epidemiological clues. *Streptococcus pneumoniae* is the most common bacterial pathogen isolated in severe CAP, followed by *Staphylococcus aureus, Haemophilus influenzae, Pseudomonas aeruginosa, Legionella species*, *Escherichia coli* and *Klebsiella pneumoniae*.[8] Common viral pathogens include influenza, respiratory syncytial virus and parainfluenza and account for up to 25% of patients hospitalised with pneumonia. Bacterial viral co-infection is uncommon but associated with higher mortality compared to viral pneumonia alone.[9]

Table 48.1

See references [1], [8], [10], [11]

Clinical Presentation

Pneumonia produces both systemic and respiratory manifestations. Common clinical findings include fever, sweats, rigours, cough, sputum production, pleuritic chest pain, dyspnoea, tachypnoea, pleural rub and inspiratory crackles. Classic signs of consolidation occur in less than 25% of cases. Multiorgan dysfunction or failure may occur depending on the type and severity of pneumonia.

The diagnosis of pneumonia may be more difficult in the elderly. Although the vast majority of elderly patients with pneumonia have respiratory symptoms and signs, over 50% may also have non-respiratory symptoms, particularly altered mental state, and over one-third may have no fever as a systemic sign of infection. [12], [13]

Investigations

Investigations for CAP include microbiological tests to identify the causative pathogen and additional laboratory and imaging tests to assess the severity of illness. Microbiological cultures should ideally be taken prior to administration of antibiotics to improve yield, but administration of antibiotics should not be delayed if timely cultures cannot be obtained as delay in antibiotic therapy is associated with an increase in mortality. [1], [14] Important investigations include:

1. Imaging: Chest X-ray (CXR) usually shows infiltrates but may be normal in 25%–30% of patients with pneumonia Lung ultrasound appears to be similarly or more sensitive, but CT imaging has superior sensitivity and specificity than CXR and may be helpful in scenarios where the CXR is normal but other clinical signs are compatible with pneumonia [15-17]

2. Arterial blood gases or pulse oximetry
3. Full blood count
4. Serum creatinine, urea and electrolytes
5. Liver function tests
6. Two sets of blood cultures [14]
7. Respiratory tract sample for urgent gram stain and culture. Tracheal aspirates are preferred over sputum samples. The usefulness of sputum tests remains debatable because of contamination by upper respiratory tract commensals. However, a single or predominant organism on a gram stain of a fresh sample or a heavy growth on culture of purulent sputum is likely to be the pathogen. The finding of many polymorphonuclear cells (PMN) with no bacteria in a patient who has not already received antibiotics can reliably exclude infection by most ordinary bacterial pathogens. Specimens should be obtained by deep cough and be grossly purulent. Ideally, the specimen should be transported to the laboratory immediately for prompt processing to minimise the chance of missing fastidious organisms (e.g. *Streptococcus pneumoniae*). Acceptable specimens (in patients with normal or raised white blood cell [WBC] counts) should contain greater than 25 PMN per low power field (LPF) and less than 10–25 squamous epithelial cells (SEC)/LPF or less than 10 PMN per SEC. These criteria should not be used for *Mycobacteria* and *Legionella* infections. Certain organisms are virtually always pathogens when recovered from respiratory secretions (Table 48.2). Patients with risk factors for tuberculosis (TB) (see Table 48.3), particularly those with cough for more than 1 month, other common symptoms of TB and suggestive radiographic changes should have sputum examined for *Mycobacterium tuberculosis* . Sputum cannot be processed for culture for anaerobes due to contamination by the endogenous anaerobic flora of the upper respiratory tract. In addition to the factors listed in Table 48.1 , foul-smelling sputum, lung abscess and empyema should raise suspicion of anaerobic infection.
8. Polymerase chain reaction (PCR) for common respiratory viruses such as influenza, parainfluenza, respiratory syncytial virus (RSV),

human metapneumovirus, adenovirus or SARS-CoV-2 on upper or lower respiratory tract sample.

9. Aspiration of pleural fluid for gram stain, culture, protein, lactate dehydrogenase (LDH), pH and leukocyte count should be considered for large pleural effusions causing impaired respiratory function, suspected empyema or loculation, thickened parietal pleura, lack of confirmatory respiratory microbiology or inadequate response to antimicrobial therapy.
10. Urinary *Legionella* antigen is specific (>95%). In patients with severe Legionnaires disease sensitivity is 88%–100% for *L. pneumophilia* serogroup 1 (the most commonly reported cause of *Legionella* infection). A positive result is virtually diagnostic of *Legionella* infection, but a negative result does not exclude it. In areas where other *Legionella* species are more common (e.g. South Australia), this test is less helpful.
11. Urinary pneumococcal antigen has moderate sensitivity (50%–80%) and high specificity (>90%).
12. PCR for bacterial pathogens on respiratory tract samples has several advantages over conventional cultures including rapid detection of bacterial pathogens (within hours), enhanced sensitivity and specificity, independence of organism viability and hence is unaffected by prior antibiotics. For example, PCR for pneumococcus is positive in 62% of blood samples from adult patients with confirmed or probable pneumococcal pneumonia, while blood cultures are positive in only 37%. [18] It can also assess for potential antimicrobial resistance by detection of resistance genes. It is most useful when performed on specimens from a normally sterile site. However, false positive results from upper respiratory tract contamination and lower respiratory tract colonisation may occur. *Mycoplasma pneumoniae* and *Chlamydophilia* PCR of lower respiratory tract samples are recommended. Multiplex PCR assays that detect multiple common respiratory bacterial or viral pathogens are now commercially available. [19] Recent evidence from a randomised control trial (RCT) suggests the use of PCR may reduce the duration of

inappropriate antibiotic therapy in pneumonia patients at risk of gram-negative pathogens. [20]

13. Human immunodeficiency virus (HIV) serology for patients who have risk factors for HIV infection or are from endemic areas.

Table 48.2

Organisms that are virtually always pathogens when recovered from respiratory secretions

Coccidiodes immitis
Blastomycoses dermatitidis
Cryptococcus neoformans

Table 48.3

Risk factors for pulmonary tuberculosis

Living in or originating from endemic area
Age (<5 yrs, middle-aged and elderly men)
Alcoholism and/or drug addiction
HIV infection
Diabetes mellitus
Lodging house dwellers
Immunosuppression
Close contact with smear-positive patients
Silicosis
Poverty and/or malnutrition
Previous gastrectomy
Smoking

Other investigations should be considered in patients with risk factors for infection with unusual organisms. Bronchoalveolar lavage (BAL) may be useful in whom sputum samples cannot be obtained from cough induced by chest physiotherapy or tracheal aspiration. BAL is indicated in immunocompromised patients and those who fail to respond to antibiotics to look for opportunistic or other rarer organisms. [21]

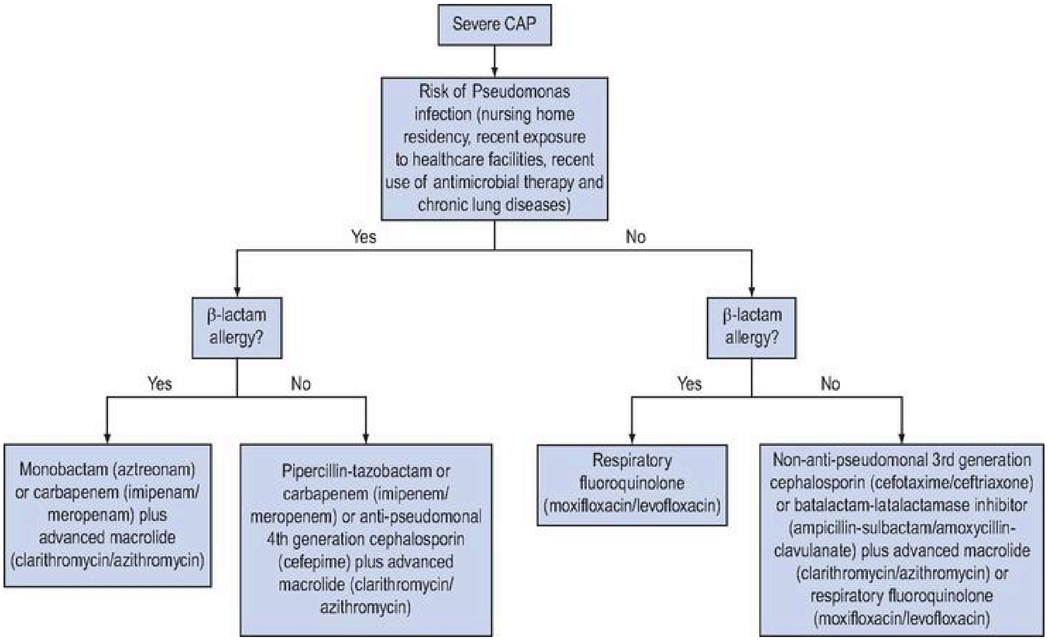
Management

General Supportive Measures

A general approach should be made towards organ support with an emphasis on correcting hypoxia. The use of nasal high-flow nasal oxygen (HFNO) was associated with lower 90-day mortality (compared to patients treated with standard oxygen therapy or non-invasive ventilation) in a randomised controlled trial of patients with acute respiratory failure, of whom 80% had pneumonia, though there was no difference in the primary outcome (need for intubation). [22] The use of non-invasive ventilation (NIV) was shown to reduce intubation rate but not mortality in a combined analysis of six RCTs. [4]

Antimicrobial Regimes

Increased mortality among those who do not receive empiric antibiotics that cover the infecting pathogen(s) is well documented. [23] Each ICU should have its own regimens tailored to the local flora and antibiotic resistance patterns. In the absence of such regimens, a suggested empirical regimen is outlined in Fig. 48.1 . This should be modified in the light of risk factors, particularly nursing home residency, recent exposure to healthcare facilities and chronic lung disease as risk factors for *Pseudomonas* infections. [1], [24], [25] Combination antimicrobials, including a macrolide, compared to monotherapy, may improve outcomes, particularly in severely ill patients with bacteraemic pneumococcal pneumonia. [26], [27] Evidence suggested a trend towards improved outcomes when a beta-lactam was combined with a macrolide rather than a fluoroquinolone. [27] Moreover, fluoroquinolones may be less appropriate in areas with a high prevalence of TB as their use may mask concurrent TB infection. Patients suspected or confirmed to be infected with Panton-Valentine Leukocidin toxin-producing *Staphylococcus aureus* (most community-acquired Methicillin Resistant Staphlococcus Aureus (MRSA) and some Methiciliin Sensitive Staphlococcus Aureus (MSSA)) may benefit from antimicrobials that also reduce toxin production (e.g. linezolid, rifampicin or clindamycin). [23] Empirical antimicrobials should be administered to pneumonia patients complicated with septic shock or sepsis within 1 hour or 3 hours of diagnosis, respectively. [28] Observational data suggests de-escalation of antibiotic therapy does not adversely affect survival or resurgence. [29-31] Spectrum of antibiotics should be narrowed (discontinue drugs targeting MRSA and *Pseudomonas*) based on cultures after 48 hours of empirical treatment. [1], [31] For the treatment of drug-resistant *Streptococcus pneumoniae* , the regimens in Fig. 48.1 are probably suitable for isolates with a penicillin minimum inhibitory concentration (MIC) less than 4 mg/L. [24] If the MIC is ≥4 mg/L an anti-pneumococcal fluoroquinolone, vancomycin, teicoplanin or linezolid should be given. [7]



Severe CAP
Risk of Pseudomonas infection (nursing home residency, recent exposure to healthcare facilities, recent use of antimicrobial therapy and chronic lung diseases)
Yes
No
β-lactam allergy?
β-lactam allergy?
Yes
No
Yes
No
Monobactam (aztreonam) or carbapenem (imipenam/meropenam) plus advanced macrolide (clarithromycin/azithromycin)
Pipercillin-tazobactam or carbapenem (imipenem/meropenem) or anti-pseudomonal 4th generation cephalosporin (cefepime) plus advanced macrolide (clarithromycin/azithromycin)
Respiratory fluoroquinolone (moxifloxacin/levofloxacin)
Non-anti-pseudomonal 3rd generation cephalosporin (cefotaxime/ceftriaxone) or batalactam-latalactamase inhibitor (ampicillin-sulbactam/amoxycillin-clavulanate) plus advanced macrolide (clarithromycin/azithromycin) or respiratory fluoroquinolone (moxifloxacin/levofloxacin)

The flowchart titled Severe Community Acquired Pneumonia details the risk of Pseudomonas aeruginosa in residents of healthcare facilities who receive antibiotic therapy or have chronic lung disease. The chart starts with a question at the top, which asks if the patient resides in a healthcare facility, received antimicrobial therapy recently, or has chronic lung disease. If the answer is yes, the chart branches to another question about a beta-lactam or lactamase allergy. If the patient has this allergy, the chart suggests Monobactam (aztreonam) or carbapenem or meropenem plus advanced macrolides, or (clarithromycin or azithromycin). If there is no lactam or lactamase allergy, the chart recommends Pipercillin-tazobactam or carbapenem (imipenem or meropenem) or an anti-pseudomonal 4th generation cephalosporin (cefepime) plus advanced macrolide (clarithromycin or azithromycin). If the initial answer about residency, therapy, or lung disease is yes, the chart moves to a question about recent fluoroquinolone use. If no, it suggests a non-anti-pseudomonal 3rd generation cephalosporin (cefotaxime or ceftriaxone) or batalactam-latalactamase inhibitor (ampicillin-sulbactam or amoxycillin clavulanate) plus advanced macrolide (clarithromycin or azithromycin) or respiratory fluoroquinolone (moxifloxacin or levofloxacin).

FIG. 48.1 Antibiotic regimes for treatment of severe community-acquired pneumonia (CAP) in critically ill patients. [1], [24], [25] *COPD* , Chronic obstructive pulmonary disease. (From Metlay JP, Waterer GW, Long AC, et al. Diagnosis and treatment of adults with community-acquired pneumonia. An Official Clinical Practice Guideline of the American Thoracic Society and Infectious Diseases Society of America. *Am J Respir Crit Care Med* . 2019;200(7):e45-e67. doi:10.1164/rccm.201908-1581ST.)

Duration of Therapy

A systematic review of 21 clinical trials including patients with severe CAP demonstrated that a short course of antibiotic treatment (less than 6 days) was as effective as a longer treatment duration (more than 7 days). [32] ERS/ESICM/ESCIDM guidelines recommend 5–7 days of appropriate antibiotics treatment if clinical stability is achieved. [4] Short courses may be suboptimal for patients with bacteraemic *Staphylococcus aureus* pneumonia, meningitis or endocarditis complicating pneumonia or infection with less common organisms (e.g. *Burkholderia pseudomallei* or fungi) or *Pseudomonas aeruginosa* . Procalcitonin may be useful to guide the discontinuation of antibiotic therapy without an adverse effect on mortality in CAP with or without sepsis. [33], [34]

Corticosteroids and Immunomodulators

The use of corticosteroids as an adjunct treatment for CAP remains controversial. Evidence on the efficacy of corticosteroids to improve survival in severe CAP is conflicting. [35-38] However, systematic review suggests corticosteroids decrease the risk of acute respiratory distress syndrome and shock, reduce mechanical ventilation and shorten the length of stay in severe CAP.[37,38] Practice guidelines currently do not recommend routine use of steroids in CAP unless complicated by refractory septic shock.[1,4]

Corticosteroids became standard treatment for severe coronavirus disease 2019 (COVID-19) pneumonia. Dexamethasone 6 mg once per day for 10 days has been shown to lower mortality of hospitalised COVID-19 patients requiring oxygen or mechanical ventilation.[39] Immunomodulators such as baricitinib and tocilizumab are recommended in addition to corticosteroids in the treatment of severe COVID-19[40,41] (see also Chapter 49).

Antiviral Treatment

Oseltamivir is recommended for patients who test positive for any influenza strain no matter the time interval between symptoms onset and positive test result. It can be included in the empirical antimicrobial regimen during an influenza epidemic if there is an expected delay in the availability of the PCR result.[4,9,42] Corticosteroids may prolong viral replication, and increase the risk of nosocomial infection and mortality for patients with influenza pneumonitis.[43] Ribavirin and palivizumab have been used in immunocompromised patients with RSV pneumonia. Remdesivir, which is a product of adenosine triphosphate analogue that inhibits viral RNA polymerases, is used for the treatment of severe COVID-19 (induction dose of 200 mg followed by maintenance dose of 100 mg daily for up to 5–10 days of total duration).[44]

Response to Therapy

Response is usually seen within 1–3 days of starting therapy; this can be assessed on the basis of improvement in respiratory symptoms, fever, leucocyte count, C-reactive protein, procalcitonin, lung compliance, oxygenation, systemic organ dysfunction and radiological infiltrates. The average time to defervescence varies with organism, severity and patient age (7 days in elderly patients, 2.5 days in young patients with pneumococcal pneumonia, 6–7 days in bacteraemic patients with pneumococcal pneumonia, 1–2 days in patients with *Mycoplasma pneumoniae* pneumonia and 5 days in patients with *Legionella* pneumonia).

Both blood and sputum cultures are usually negative within 24–48 hours of treatment, although *Pseudomonas aeruginosa* and *Mycoplasma pneumoniae* may persist in the sputum despite effective therapy. Changes in radiological infiltrates often lag behind clinical improvement with the rate of improvement depending on the type of organism, severity of illness, age and co-morbidities. The CXRs of most young or middle-aged patients with bacteraemic pneumococcal pneumonia are clear by 4 weeks but the resolution is slower in elderly patients and patients with underlying illness, extensive pneumonia on presentation or *Legionella pneumophilia* pneumonia.

If the patient fails to respond to treatment, consider the possible causes of unresolving pneumonia (Fig. 48.2). Useful evaluation of possible causes of unresolved pneumonia includes performing clinical examination to assess fluid status, features of autoimmune diseases, malignancy and extra-pulmonary infections, performing echocardiography to assess cardiac function, checking autoimmune and tumour markers, sending paired serology for known and unknown emergent pathogens where routine microbiological workup was negative, imaging the chest and/or other regions to look for structural lesions or other sources of infection, draining pleural effusions, performing bronchoalveolar lavage (Table 48.4) to look for opportunistic organisms and considering transbronchial or open lung biopsy for histological diagnosis.

The diagram details the infection process of the causative organism in pneumonia across four sections, arranged from top to bottom. The first section, labelled Host factor causing treatment failure, depicts a close-up view of a pathogen that interacts with cells in the respiratory tract.

The following parts are labelled: tumour, foreign body, bronchial lumen, and inadequate immune response. The second section, labelled Diagnosis other than pneumonia, presents a magnified view of the upper respiratory tract with the following labelled parts: interstitial lung disease, fibroblastic focus, fibrosis, honeycombing, cross-section of alveoli, pulmonary endema with fluid. The third section, labelled Complications of Pneumonia, depicts a lung with a highlighted area indicative of infection with lung abscess and empyema, alongside a depiction of fluid accumulation in the alveolar spaces. The fourth section, labelled Inadequate Eradication of the Causative Organism, includes three subparts from left to right: more than one organism, a resistant organism, and an inadequate antibiotic dose.

FIG. 48.2 Causes of unresolving pneumonia.

Table 48.4

Prediction of Adverse Outcome and Admission to Intensive Care Unit

The CURB65 score can be used to risk-stratify patients. Patients with three or more of the following features have a greater than 15% mortality risk: new confusion or abbreviated mental test score ≤8; urea greater than 7 mmol/L (blood urea nitrogen >19.6 mg/dL); low blood pressure, diastolic ≤60 mm Hg or systolic ≤90 mm Hg; age ≥65 years.

Hospital-acquired pneumonia and ventilator-associated pneumonia

Hospital-acquired pneumonia (HAP) is defined as pneumonia with an onset occurring after 48 hours of hospital admission. [47] It occurs in 0.5%–5% of hospitalised patients, with a higher incidence in certain groups (e.g. postoperative and ICU patients). [48] Diagnosis may be difficult as many non-infectious conditions (e.g. atelectasis, aspiration, heart failure, pulmonary haemorrhage and cancer) can cause chest infiltrates. Identification of the organism responsible is even more difficult than in patients with CAP due to the high incidence of oropharyngeal colonisation by gram-negative bacteria.

Ventilator-associated pneumonia (VAP) is pneumonia arising after 48 hours of invasive mechanical ventilation. The reported incidence of VAP is 10%–20% for those who receive mechanical ventilation for more than 48 hours. [49]

Pathogenesis

HAP/VAP is thought to result from microaspiration of bacteria colonising the upper respiratory tract (Fig. 48.3). Other routes of infection include macroaspiration of gastric contents, inhaled aerosols, haematogenous spread, spread from pleural space and direct inoculation from ICU personnel.

The diagram depicts a cutaway view of the human torso. It centrally features the respiratory system. The nose and mouth lead into the pharynx and trachea. The trachea extends downwards into the bronchial tubes and the two lungs. Below the lungs is the diaphragm. A key element is an endotracheal tube inserted into the trachea and the accumulation of gram-negative flora. On the left side of the diagram, insets indicate impaired mucociliary clearance with ciliated epithelial cells, an infected lung, and loss of cough reflex. On the right side, a detailed inset titled Sources of Ventilator-Associated Pneumonia Pathogens has three sections. Section A depicts biofilm formation in the endotracheal tube. Section B presents a pool of secretions above the cuff of the endotracheal tube, with drainage of sterile droplets. Section C, titled Haematological spread, provides a magnified view of an alveolus, an air space filled with fluid, surrounded by capillaries.

FIG. 48.3 Pathogenesis of ventilator-associated pneumonia. *VAP* , Ventilator-associated pneumonia.

Clinical Diagnosis

Diagnosis is based on the findings of new or progressive chest infiltrates plus either clinical features with simple laboratory investigations or the results of quantitative microbiology. In clinical terms, HAP/VAP is diagnosed by the finding of a new radiological infiltrate with two of either core temperature ≥ 38°C, WBC count $\geq 12 \times 10^{5}$ /L or purulent sputum. However clinical criteria only have sensitivity of 69% and specificity of 75% for VAP. [50] Other scoring systems such as the Clinical Pulmonary Infection Score also lack diagnostic performance for VAP. [51]

Investigations

These are broadly similar to those required in CAP, additional points include:

- Imaging: although studies that used histological diagnosis as the gold standard have demonstrated that pneumonia may be present despite a normal CXR, most definitions of HAP/VAP require the presence of new persistent chest infiltrates. CT imaging has superior sensitivity and specificity than CXR and may be helpful in scenarios where the CXR is normal but other clinical signs are compatible with pneumonia. [17]
- Respiratory secretions: considerable controversy surrounds the issue of whether invasive sampling of respiratory secretions is necessary,

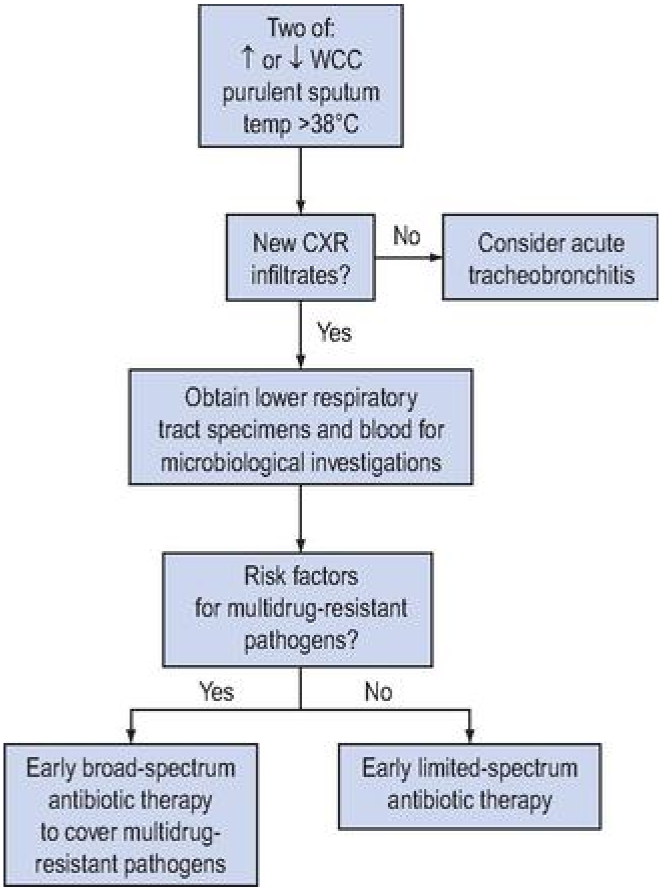
and whether quantitative culture improves diagnostic accuracy. [47] Whether invasive (bronchoscopic BAL, protected specimen brushing or blind bronchial miniBAL, see Table 48.4) or non-invasive (tracheal aspirates) sampling is used, empiric broad-spectrum antibiotics should be started while results are awaited. The results of microbiological analysis of specimens are used to either stop antibiotics or narrow the spectrum. [47] Using histopathology as reference standard, tracheal aspirate using semi-quantitative culture has higher sensitivity but lower specificity compared to quantitative tracheal aspirate ($\geq 10^5$ colony-forming unit [CFU]/mL) or BAL ($\geq 10^4$ CFU/mL). Quantitative BAL and quantitative tracheal aspirate have similar sensitivity (approximately 50%) and specificity (approximately 80%). A meta-analysis of randomised trials shows that sampling sites and culture techniques do not affect clinical outcomes, such as the duration of mechanical ventilation, the ICU length of stay or mortality. [47] The latest 2016 IDSA/ATS guidelines on HAP/VAP favour the use of non-invasive sampling with semi-quantitative culture for the diagnosis of VAP *(weak recommendation, low quality of evidence)* . While tracheal aspirates may predominantly reflect the organisms colonising the upper airway, they may be useful in indicating which organisms are not responsible for pneumonia, thus allowing the antimicrobial cover to be narrowed. [47] This interpretation is based on the premise that the predominant route of infection is via the upper respiratory tract. From this, it can be assumed that if the organism is not present in the upper respiratory tract, the probability of it being present in the lung parenchyma is low. Certain organisms are virtually always pathogens when recovered from respiratory secretions (see Table 48.2). Of note, the respiratory specimens should be processed within 2 hours if kept at room temperature and within 24 hours if kept at 4°C.

- Blood cultures: Blood cultures should be taken from all patients with HAP/VAP. Although only 15% of VAP patients are bacteraemic, this is associated with a worse prognosis. [52] At least

25% of positive blood cultures in patients with suspected VAP are from non-pulmonary sources of sepsis, with important implications in antimicrobials treatment and source control.[34,53]

Management

Early appropriate treatment with antimicrobials results in a reduction in morbidity and mortality.[3] The initial selection of antimicrobials is based on risk factors for multidrug-resistant (MDR) organisms and the local ICU/hospital antibiogram (Fig. 48.4 , Table 48.5). *Staphylococcus aureus* , *Pseudomonas aeruginosa* and other gram-negative bacilli should be covered in all empirical therapies *(strong recommendation, low-quality evidence)* . The results of microbiological investigations are used to narrow antimicrobial cover later. Treatment should be reassessed after 2–3 days or sooner if the patient deteriorates (Fig. 48.5).



Two of:
↑ or ↓ WCC
purulent sputum
temp >38°C
New CXR infiltrates?
No
Consider acute tracheobronchitis
Yes
Obtain lower respiratory tract specimens and blood for microbiological investigations
Risk factors for multidrug-resistant pathogens?
Yes
No
Early broad-spectrum antibiotic therapy to cover multidrug-resistant pathogens
Early limited-spectrum antibiotic therapy

The flowchart depicts a diagnostic pathway for respiratory infections. It begins with the criteria of two of increased or decreased blood cell count, purulent sputum or temperature above thirty eight degrees Celsius. If these criteria are met, the next step is to check for new chest radiograph infiltrates. If there are no new chest radiograph infiltrates, consider acute tracheobronchitis. If there are new chest radiograph infiltrates, obtain lower respiratory tract specimens and blood for microbiological investigations. The next step is to assess risk factors for multidrug-resistant pathogens. If risk factors are present, initiate early broad-spectrum antibiotic therapy to cover multidrug-resistant pathogens. If no risk factors are present, initiate early, limited-spectrum antibiotic therapy.

FIG. 48.4 An outline of initial management of HAP/VAP based on a non-invasive clinical approach. *CXR* , Chest x-ray; *HAP* , hospital-acquired pneumonia; *VAP* , ventilator-associated pneumonia.

Table 48.5

IDSA/ATS Recommendations for initial empiric treatment of HAP [90]

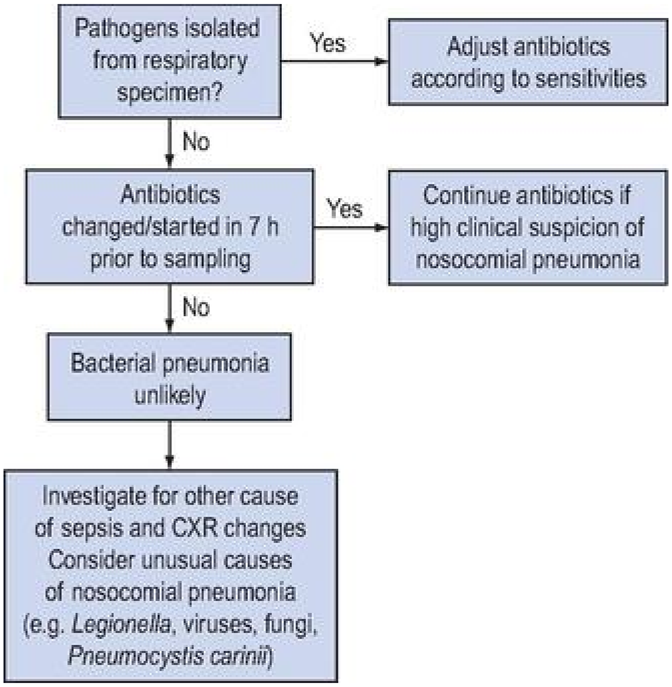
CLINICAL CONTEXT	ANTIBIOTICS
Not at high risk of mortality [a]	*One of the following:* Piperacillin-tazobactam 4.5 g IV q6h OR Cefepime 2 g IV q8h OR Levofloxacin 750 mg IV q24h Ciprofloxacin 400 mg IV q8h OR Meropenem 1 g IV q8h Imipenem 500 mg IV q6h
High risk of mortality or received IV antibiotics during the prior 90 days [c]	*Two of the following (avoid 2 β-lactams):* [c] Piperacillin-tazobactam 4.5 g IV q6h OR Cefepime 2 g IV q8h OR Levofloxacin 750 mg IV q24h Ciprofloxacin 400 mg IV q8h OR Meropenem 1 g IV q8h Imipenem 500 mg IV q6h OR Amikacin 15–20 mg/kg IV q24h Gentamicin 5–7 mg/kg IV q24h

CLINICAL CONTEXT	ANTIBIOTICS
	Tobramycin 5–7 mg/kg IV q24h OR Aztreonam 2 g IV q8h
In addition to either of the above and at risk of MRSA [b]	Either of the above PLUS: Vancomycin loading 25–30 mg/kg, 15 mg/kg q12–8h OR Linezolid 600 mg q12h

[a] High risk of mortality includes any patient on ventilatory support due to pneumonia or has septic shock.

[b] Indications for MRSA coverage include intravenous antibiotic treatment during the prior 90 days, known MRSA carrier, or treatment in a unit with >20% MRSA amongst *Staphylococcus aureus* isolates. If MRSA coverage is omitted, the antibiotic regimen should include coverage for MSSA.

[c] Empirical use of dual therapy to cover high likelihood of gram-negative pathogens is controversial but does reduce the chance of inappropriate initial coverage.



Pathogens isolated from respiratory specimen?
Yes
Adjust antibiotics according to sensitivities
No
Antibiotics changed/started in 7 h prior to sampling
Yes
Continue antibiotics if high clinical suspicion of nosocomial pneumonia
No
Bacterial pneumonia unlikely
Investigate for other cause of sepsis and CXR changes Consider unusual causes of nosocomial pneumonia (e.g. *Legionella*, viruses, fungi, *Pneumocystis carinii*)

The flowchart depicts the step-by-step process to manage nosocomial pneumonia based on a non-invasive clinical approach. The first step involves checking if the pathogens are isolated from the respiratory specimen. If yes, adjust antibiotics according to sensitivities. If no, antibiotics are changed or started 7 hours prior to sampling. If there is any symptom, continue antibiotics if high clinical suspicion of nosocomial pneumonia. If not, there is an unlikely situation of bacterial pneumonia, leading to investigation for other causes of sepsis and C X R changes. Consider unusual causes of nosocomial pneumonia, for example, Legionella, viruses, fungi, and Pneumocystis carinii.

FIG. 48.5 Subsequent management of nosocomial pneumonia based on a non-invasive clinical approach. *CSR* , Chest x-ray.

Duration of Therapy

Current IDSA/ATS guidelines recommend 7 days rather than 8–15 days of antimicrobial treatment for both VAP and HAP *(strong recommendation, moderate-quality evidence)* .[47] Systematic reviews confirmed no difference in important clinical outcomes such as mortality, length of stay and duration of mechanical ventilation. Short-course antibiotics increase 28-day antibiotic-free days and decrease recurrent VAP due to MDR organisms. There is a concern in VAP caused by non-glucose fermenting gram-negative bacilli (*Pseudomonas sp.* and *Acinetobacter sp.*) that 8-day therapies may have more recurrent infection when compared to 15-day therapies.[54], [55] Although this finding is not universal, caution should be applied when considering short courses of antibiotics for non-glucose fermenting gram-negative bacilli. Serial measurement of procalcitonin can be used to guide the duration of antibiotics in VAP by reducing antibiotic exposure without adverse effects on patient outcomes.[34], [56]

Response to Therapy

Clinical improvement is usually not apparent for 48–72 hours and therapy should not be changed at this time. The CXR is of limited value for assessing response: initial deterioration is common and improvement often lags behind clinical response. However, a rapidly deteriorating CXR pattern with a less than 50% increase in size of infiltrate in 48 hours, new cavitation or a significant new pleural effusion should raise concern. If a patient fails to respond, consider the diagnosis, host factors (e.g. immunosuppressed and debilitated), bacterial factors (e.g. virulent organism) and therapeutic factors (e.g. wrong drug and inadequate dose). Review the antibiotics and repeat cultures. It may be useful to broaden the antimicrobial cover while waiting for the results of investigations. Consider invasive sampling of respiratory secretions, CT or ultrasound of the chest (to look for empyema or abscess), another source of infection, an open lung biopsy to confirm aetiology of VAP or reveal alternative non-infective causes of respiratory failure, the latter of which may respond to corticosteroids if an infective cause has been ruled out.

Mortality and morbidity attributable to ventilator-associated pneumonia

Although substantial morbidity and mortality have been associated with VAP, causal inference is difficult to establish.[49] It should be noted that patients who develop VAP tend to be more severely ill and at a higher risk of death, not only at the time of ICU admission but also throughout the course of their illness. While VAP is associated with a significantly longer ICU length of stay (mean of 6.1 days; 95% CI: 5.32–6.87), mechanical ventilation and increased health care cost, recent studies suggest that mortality directly attributable to VAP is around 3%–17%.[47], [49] However, in a competing analysis, the increased risk of dying in the ICU in patients with VAP was concluded to be merely due to the results of prolonged ICU length of stay rather than a direct effect on VAP on mortality.[57]

Prevention

Several guidelines for the prevention of VAP and HAP have been published, but these vary in the advice given. A consensus summary, based on literature review followed by a Delphi approach, is given in Table 48.6 .[58] A short course of prophylactic antibiotics in mechanically ventilated patients who had out-of-hospital cardiac arrest has been shown to reduce the risk of early but not late VAP.[59]

Table 48.6

Consensus strategies for prevention of ventilator-associated pneumonia [91]

Positioning	**Nurse in semirecumbent position (≥30 degrees)**
Minimise duration of invasive mechanical ventilation	Assess daily for readiness to wean using spontaneous awakening trials and spontaneous breathing trials Facilitate use of non-invasive ventilation
Suctioning	Use subglottic suctioning in patients expected to be intubated for >72 h Use closed endotracheal suctioning and change catheters only as needed Use standard precautions while suctioning respiratory tract secretions Avoid non-essential tracheal suctioning
Ventilator circuit	Change ventilator circuits only when damaged or soiled. Remove condensate from circuits, keeping circuit closed during removal and making sure condensate does not drain towards patient Change heat and moisture exchangers every 5–7 days or if clinically indicated
General care	Oral care at least six times per day, with chlorhexidine at least twice per day Use an early mobilisation protocol Avoid gastric overdistension

Positioning	**Nurse in semirecumbent position (≥30 degrees)**
General infection control measures	Perform hand hygiene Avoid use of prophylactic systemic antimicrobials

Tuberculosis

Pulmonary *Mycobacterium tuberculosis* (MTB) is the most common site of tuberculosis (TB) infection. The main risk factors are listed in Table 48.3 . Typical clinical features include fever, sweating, weight loss, lassitude, anorexia, cough productive of mucoid or purulent sputum, haemoptysis, chest wall pain, dyspnoea, localised wheeze and apical crackles. Patients may also present with unresolved pneumonia, pleural effusions, spontaneous pneumothorax and hoarseness or with enlarged cervical nodes or other manifestations of extra-pulmonary disease. In a recent large retrospective study, in-hospital mortality was 41.1% for ICU patients with TB. [60] TB patients who require mechanical ventilation, renal replacement therapy and vasopressors have mortality rates of up to 80%. The presentation and management of TB in HIV-positive patients is different (see later).

Investigation of Pulmonary Tuberculosis

Identification of Mycobacteria Tuberculosis

At least three sputum samples should be collected for fluorescent microscopy for acid-fast bacilli (AFB) and culture. [61,62] If sputum is not available, bronchoalveolar lavage taken at bronchoscopy and gastric lavage or aspirate samples should be obtained. Gastric aspirates need to be neutralised immediately upon collection. Bronchoscopy and transbronchial biopsy may be useful in patients with suspected TB but who have a negative sputum smear. Pleural biopsy is often helpful and mediastinoscopy is occasionally needed in patients with mediastinal lymphadenopathy. Part of any biopsy specimen should always be sent for culture. The use of MTB

PCR improves the diagnostic yield and facilitates early treatment, especially since MTB culture results may take weeks. In respiratory samples, PCR has a sensitivity of 83.9% (compared to 59.2% for the Ziehl-Neelsen stain) with a specificity of 98.1% when compared to the gold standard of MTB cultures. [60] The use of Xpert MTB/RIF gene probe can also simultaneously identify resistance to rifampicin. As rifampicin is strongly associated with isoniazid resistance, the system can give a strong indication of multi-drug resistance. [63]

Chest X-Ray

A normal CXR almost excludes TB (false negative in 4.8%) in immunocompetent patients but endobronchial lesions may not be apparent, and early apical lesions can be missed. [61] Common appearances include patchy/nodular shadowing in the upper zones (often bilateral), cavitation, calcification, hilar or mediastinal lymphadenopathy (may cause segmental or lobar collapse), pleural effusion, tuberculomas (dense round or oval shadows) and diffuse fine nodular shadowing throughout the lung fields in miliary TB. Inactivity of disease cannot be inferred from the CXR alone and respiratory samples should be sent for identification of TB. CXR appearances in patients with HIV and TB may not have typical CXR features of TB.

Treatment of Pulmonary Tuberculosis

The decision to initiate anti-TB treatment should be based on the level of clinical suspicion, imaging, the results of the Ziehl-Neelsen stain, MTB PCR and mycobacterial culture. If the initial clinical suspicion is strong and the patient is seriously ill attributable to possible TB, treatment should be initiated promptly, sometimes before the result of microbiological results. [64] A negative Ziehl-Neelsen stain should not delay initial treatment if clinical suspicion remains high as delay in treatment is associated with higher mortality. Supporting features include chronic cough, weight loss, night sweats, characteristic radiological imaging, emigration from a high-incidence country, no other immediate diagnosis and a positive tuberculin test. Combination chemotherapy consisting of four drugs is necessary for maximal efficacy. Treatment is divided into the initial phase and the continuation phase. The most commonly used initial regimen consists of 8 weeks of rifampicin 600 mg daily (450 mg for patients <50 kg), isoniazid 300 mg daily, pyrazinamide 2 g daily (1.5 g for patients <50 kg) and ethambutol 15 mg/kg daily as an initial phase treatment. Ethambutol should only be used in patients who have reasonable visual acuity and who are able to appreciate and report visual disturbances. This excludes patients who require sedation. Visual acuity and colour perception must be assessed (if ethambutol is to be used) and liver and renal function checked before treatment is started. However, critically ill patients with TB often have liver or renal impairment. Second-line treatment with fluoroquinolone, aminoglycoside and ethambutol can be used for patients with deranged liver function, which requires avoidance of hepatotoxic isoniazid and rifampicin, and workup for the causes. Pyrazinamide, ethambutol and aminoglycoside are renally excreted and necessitate dose adjustment.[65,66] Pyridoxine 10 mg daily should be given to prevent isoniazid-induced neuropathy to those at increased risk (e.g. patients with diabetes mellitus, chronic renal failure or malnutrition or alcoholic or HIV-positive patients). Steroids are only recommended for patients with concomitant meningitis or pericardial effusion and, possibly, for patients with TB pleural effusions or endobronchial disease.[66,67]

Infection Control

Patients admitted to an ICU with infectious TB or suspected of having active pulmonary TB should be managed in a negatively pressured airborne isolation room.[68,69] Patients should be considered infectious if they are coughing or undergoing cough-inducing procedures, if they have positive AFB smears and they are not on or have just started chemotherapy or have a poor clinical or bacteriological response to chemotherapy. Patients with non–drug-resistant TB are usually non-infectious after 2 weeks of treatment that includes rifampicin and isoniazid.[68] As TB is spread through aerosols it is probably appropriate to isolate patients who are intubated, even if only their bronchial alveolar lavages or aspirates are smear positive. Staff caring for patients who are smear positive should wear personal protective equipment including a fit-tested negative-pressure respirator (N95, FFP2 or higher). The use of a powered air-purifying respirator should be considered when bronchoscopy is being performed, particularly if the patient has not received effective treatment, is smear positive and if the bronchoscopy is being carried out in a room with less than 12 air changes per hour.[69]

Pneumonia in the Immunocompromised

The lungs are amongst the most frequent target organs for infectious complications in the immunocompromised. The incidence of pneumonia is highest amongst patients with haematological malignancies, bone marrow transplant (BMT) recipients and patients with AIDS.

The speed of progression of pneumonia and the type of immune defect provide clues to the aetiology. Bacterial pneumonias progress rapidly (1–2 days), while fungal and protozoal pneumonias are less fulminant (several days to a week or more). Viral pneumonias are usually not fulminant, but on occasion, they may develop quite rapidly. Bronchoscopy examination and bronchoalveolar lavage are essential investigations in these patients. Recent systematic reviews found early NIV or HFNO may reduce the need for intubation amongst immunocompromised patients with pneumonia.[70], [71] There is also evidence of improved survival with the use of NIV, but not HFNO.

Pneumocystis Jiroveci Pneumonia

Most cases of *Pneumocystis jiroveci* pneumonia (PJP) occur in patients with HIV who are not receiving HIV care or who have advanced immunosuppression, or in patients with other causes of immunosuppression (e.g. haematological malignancy).[72] The onset is usually insidious with dry cough, dyspnoea and fever on a background of fatigue and weight loss. Crackles in the chest are rare. A rise in lactate dehydrogenase is common but non-specific. Approximately 15% of patients have a concurrent cause for respiratory failure (e.g. Kaposi sarcoma, cytomegalovirus, TB and bacterial pneumonia). Useful investigations are:

1. CXR: classical appearance is diffuse bilateral perihilar interstitial shadowing, but in the early stages this is very subtle and easily missed. The initial CXR is normal at 10%. In a further 10%, the changes are atypical with focal consolidation or coarse patchy shadowing. None of the changes are specific to PJP. Pleural effusions, hilar or mediastinal lymphadenopathy are unusual in PJP but are common in mycobacterial infection, Kaposi's sarcoma or lymphoma.
2. Induced sputum: In this non-invasive technique, the patient inhales nebulised hypertonic saline from an ultrasonic nebuliser. This provokes bronchorrhoea and the patient coughs up material containing cysts and trophozoites. This is time-consuming and requires meticulous technique, and is less sensitive than bronchoscopy. The possibility of concurrent TB should be considered and steps taken to minimise the infective risk to other patients and healthcare workers.
3. Bronchoscopy with bronchoalveolar lavage leads to the diagnosis in over 90% of cases. Specimens should be sent for microscopy with direct fluorescent antibody staining. PCR is a sensitive method of detecting PJP but may not be able to distinguish colonisation from infection. The role of PCR in diagnosing PJP is particularly useful in non–HIV immunocompromised patients, in whom conventional microscopy and staining of induced sputum and BAL have a lower sensitivity than in HIV patients. [22]

Anti-pneumocystis treatment should be started as soon as the diagnosis is suspected. Treatment should not be delayed to obtain specimens as organisms persist in specimens for days to weeks after effective treatment is initiated. The treatment of choice is trimethoprim plus sulphamethoxazole (co-trimoxazole) 20 mg/kg per day + 100 mg/kg per day for 3 weeks. Intravenous administration of co-trimoxazole requires large volume dilution, thus it is important to review fluid balance daily to avoid excessive fluid gain. Adjunctive steroids should be given as soon as possible and within 72 hours to all HIV-immunosuppressed patients with PJP. Adjunctive steroids may be considered for non-HIV patients with PJP who require high-flow oxygen or mechanical ventilation, although the evidence that steroids improve outcomes in non-HIV patients is weaker when compared to those with HIV. [73] Usual regimen is prednisolone 40 mg orally twice daily for 5 days followed by 20 mg twice daily for 5 days and then 20 mg/day until the end of PJP treatment. Side effects of co-trimoxazole are common (nausea, vomiting, skin rash, myelotoxicity, nephrotoxicity and hepatotoxicity). The dose should be reduced by 25% if the WBC count falls. Patients who are intolerant of co-trimoxazole should be treated with pentamidine 4 mg/kg per day intravenously or primaquine with clindamycin.

Response to treatment is usually excellent, with a response time of 4–7 days. If the patient deteriorates or fails to improve by 8 days of treatment: consider treating co-infection, repeat bronchoscopy with BAL for alternative diagnosis, repeat imaging and consider diuretics for pulmonary oedema caused by large volume of fluid from intravenous co-trimoxazole. Approximately 70% of patients with HIV-related PJP, but only 40% of patients with non–HIV-related PJP, who require mechanical ventilation survive hospital discharge. [74]

Antiretroviral therapy is normally started within 2 weeks of diagnosis in patients who present with HIV-related PJP as early antiretroviral therapy is associated with better outcomes. However, as this may precipitate paradoxical immune reconstitution inflammatory syndrome, a multidisciplinary approach with infectious disease specialists should be taken for initiation of antiretroviral therapy in critically ill patients with HIV. Furthermore, antiretroviral therapy is challenging in ICU patients due to unpredictable absorption of oral medications, lack of parenteral antiretroviral therapy and potential drug interactions. [75]

Bacterial Pneumonia

This is the most common cause of acute respiratory failure in HIV-positive patients. Bacterial pneumonia is more common in HIV-infected patients than in the general population and tends to be more severe. *Streptococcus pneumoniae, Haemophilus influenza, Pseudomonas aeruginosa* and *Staphylococcus aureus* are the most common organisms. *Nocardia* and

Gram negatives should also be considered. Atypical pathogens (e.g. *Legionella*) are rare. The response to appropriate antibiotics is usually good but may require protracted courses of antibiotics because of the high tendency to relapse. Patients with severe immunodeficiency (CD4$^+$ T lymphocyte count <100/µL) and a history of *Pseudomonas* infection or bronchiectasis or neutropenia should receive antibiotics that cover *Pseudomonas aeruginosa* as well as other gram negatives. The possibility of concurrent PJP or TB should be excluded.

Tuberculosis

TB may be the initial presentation of AIDS, particularly in sub-Saharan Africa. The pattern of TB in HIV patients depends on the degree of immunosuppression. In patients with CD4$^+$ T lymphocytes >350 cells/µL, the clinical presentation is similar to TB in non–HIV-infected patients although extra-pulmonary disease is more common.[75] In patients with CD4$^+$ T lymphocytes less than 200 cells/µL, extra-pulmonary disease (pleuritis, pericarditis and meningitis) is common. In these patients, CXR findings may be atypical with lower and middle lobe disease or even normal and respiratory samples should be sent for Ziehl-Neelsen stain, TB PCR and culture to assess for active TB.[76]

Response to treatment is usually rapid. Initial treatment should be the same as non–immunocompromised patients, except in HIV-infected patients receiving antiretrovirals. Management of TB in these patients is complex due to numerous drug interactions, and consultation with an expert in the treatment of HIV-related TB should be strongly considered.

Cytomegalovirus (CMV) Pneumonitis

The risk of infection is highest following haematological stem cell transplantation, followed by lung transplantation, pancreas transplantation and then liver, heart and renal transplantation and advanced AIDS.[77, 78] If both the recipient and the donor are seronegative then the risk of both infection and disease are negligible. If the recipient is seropositive, the risk of infection is approximately 70% but the risk of disease is only 20%, regardless of the serostatus of the donor. However, if the recipient is seronegative and the donor is seropositive the risk of disease is 70%. If steroid pulses and antilymphocyte globulin are given for the treatment of acute rejection, the risk of developing disease is markedly increased. CMV pneumonitis may be the result of primary infection or reactivation of latent infection. It is clinically important, but often difficult, to distinguish between CMV infection and CMV disease, and a definitive diagnosis can only be made histologically. Quantitative PCR can be used to quantify viral load in blood and BAL fluid, which will aid the distinction. Treatment consists of intravenous ganciclovir for at least 14 days. Foscarnet can be used if ganciclovir is contraindicated or fails.

Fungal Pneumonia

Fungi are rare but important causes of pneumonia. They can be divided into two main groups based on the immune response required to combat infection with these organisms. Histoplasma, blastomycosis, coccidioidomycosis, paracoccidioidomycosis and cryptococcus require specific cell-mediated immunity for their control and thus, in contrast to infections, which are controlled by phagocytic activity, the diseases caused by these organisms can occur in otherwise healthy individuals, although they cause much more severe illness in patients with impaired cell-mediated immunity (e.g. patients infected with HIV and organ transplant recipients). With the exception of cryptococcus, these organisms are rarely seen outside North America. Aspergillus and mucor spores are killed by non-immune phagocytes, so these fungi rarely result in clinical illness in patients with normal neutrophil numbers and function.

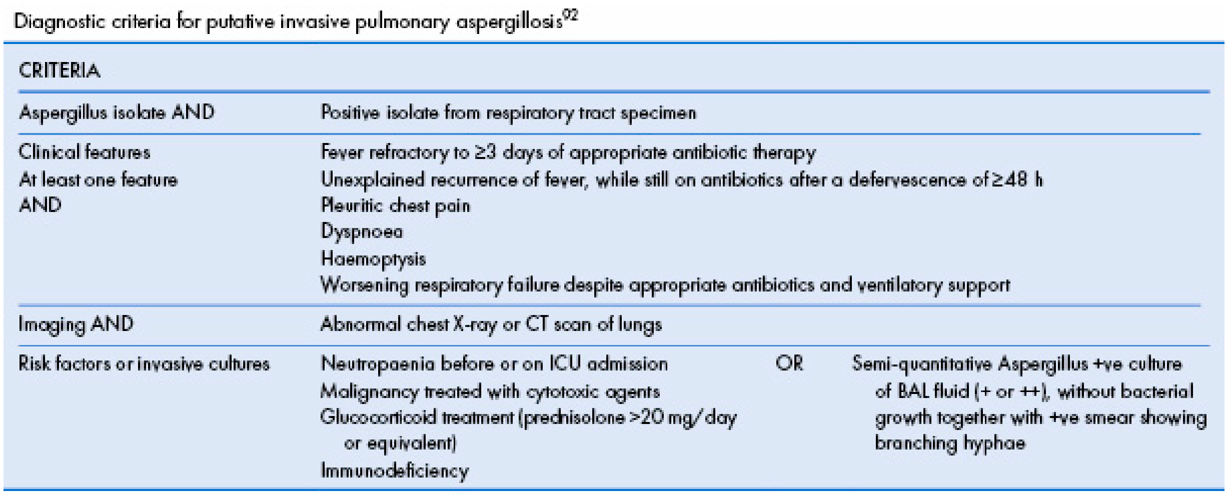
Candidiasis

Primary *Candida* pneumonia (i.e. isolated lung infection) is uncommon [79-81] and the isolation of *Candida* from respiratory secretions most commonly reflects benign colonisation of the airway. Where it is associated with infection, pulmonary lesions are usually one of the many manifestations of disseminated candidiasis involving multiple organs. Echinocandins are the recommended first-line treatment for the critically ill.

Invasive Aspergillosis

Invasive aspergillosis was previously believed to be almost exclusively associated with severe immunocompromise. However, recent data suggest that the majority of cases in the ICU are not severely immunocompromised, with chronic obstructive pulmonary disease and decompensated liver disease being significant patient risk factors. [82] Exposure to construction, demolition or renovation work is an important environmental risk factor. Definitive diagnosis requires both histological evidence of acute-angle branching, septated non-pigmented hyphae measuring 2–4 µm in width and cultures yielding *Aspergillus* species from biopsy specimens of involved organs, but this is rarely practical in critically ill patients. The diagnostic criteria for putative invasive pulmonary aspergillosis (Table 48.7), provide a more useful guide for clinicians caring for critically ill patients. The criteria have a 61% specificity and 92% sensitivity for invasive pulmonary aspergillosis. [83] Galactomannan antigen detection has high specificity for invasive pulmonary aspergillosis in both serum and BAL fluid but has much greater sensitivity in BAL fluid. Early intravenous treatment is important. First-line therapy is voriaconazole. Liposomal amphotericin is an alternative and echinocandins can be used as salvage therapy. [84]

Table 48.7



Diagnostic criteria for putative invasive pulmonary aspergillosis[92]

CRITERIA			
Aspergillus isolate AND	Positive isolate from respiratory tract specimen		
Clinical features At least one feature AND	Fever refractory to ≥3 days of appropriate antibiotic therapy Unexplained recurrence of fever, while still on antibiotics after a defervescence of ≥48 h Pleuritic chest pain Dyspnoea Haemoptysis Worsening respiratory failure despite appropriate antibiotics and ventilatory support		
Imaging AND	Abnormal chest X-ray or CT scan of lungs		
Risk factors or invasive cultures	Neutropaenia before or on ICU admission Malignancy treated with cytotoxic agents Glucocorticoid treatment (prednisolone >20 mg/day or equivalent) Immunodeficiency	OR	Semi-quantitative Aspergillus +ve culture of BAL fluid (+ or ++), without bacterial growth together with +ve smear showing branching hyphae

BAL , Bronchoalveolar lavage; *CT* , computed tomography; *ICU* , intensive care unit.

Parapneumonic Effusion and Empyema

This may be a simple parapneumonic effusion that resolves with appropriate treatment of the underlying pneumonia, or a complicated parapneumonic effusion that develops into an empyema unless drained. Complicated effusions tend to develop 7–14 days after initial fluid formation. Empyema is defined as collection of pus in the pleural space.

Aetiology

This most commonly follows bacterial pneumonia and parapneumonic effusion. [85] Other causes include bronchial carcinoma, oesophageal rupture, extension of subdiaphragmatic infection, chest trauma, mediastinitis and infections of the thoracic or cervical spine. Aerobic gram-negative rods most commonly *Klebsiella pneumoniae and Pseudomonas aeruginosa* are responsible for 78% of cases while gram-positive cocci including

Staphylococcus aureus and *Streptococcus* spp, and *Bacteroides* spp, the anaerobic bacteria are other possible causative organisms.[86]

Diagnosis

The diagnosis should be considered in all patients with a pleural effusion and pneumonia or unexplained sepsis. Failure of clinical improvement within a few days in a patient with pneumonia should prompt investigation to identify a pleural effusion. Imaging should include a CXR and ultrasound. Ultrasound may reveal effusions that are obscured by consolidation on the CXR and echogenic fluid, septation and loculation within the effusion. CT imaging may reveal loculations, pleural enhancement and thickening, demonstrate the underlying cause and distinguish between an abscess and an empyema. The diagnosis of empyema is confirmed by the aspiration of pus. In the absence of pus, measure the pleural fluid pH and LDH. A pH <7.2 or LDH >1000 IU/L indicates complicated parapneumonic effusions that require drainage.[85] Pleural fluid taken at the time of pleurocentesis should be sent for culture.

Treatment

The mainstay of treatment is early image-guided drainage of complicated parapneumonic effusion and empyema. The traditional belief is that small-bore catheters are ineffective for drainage due to fibrin septation and increased viscosity of the fluid or pus. However, observational data suggests small sized drain (<14Fr) is as effective as large sized drain of more than 15 or 20Fr, as long as regular flushing of the drain (e.g. 30 mL normal saline every 8 hours) is performed to reduce the risk of drain occlusion.[87] The adequacy of drainage should be monitored with serial imaging. Insertion of additional drains or exchanging existing drains with larger calibre may be required for undrained loculated collections. Intrapleural-tissue-plasminogen-activator and DNase may be beneficial in patients with unresolved loculated effusions but are not routinely indicated in patients with early complicated parapneumonic effusion or empyema. Failure to achieve complete drainage or failure to improve should prompt a referral to a thoracic surgeon for surgical drainage. Antibiotics have only an adjunctive role. Broad-spectrum antibiotic regimes with gram positive, gram negative and anaerobic cover should be used until the results of microbiological analysis of the aspirated pus are available.

COVID-19

Hugh Montgomery, Simon Stallworthy and Sampath Weerakkody

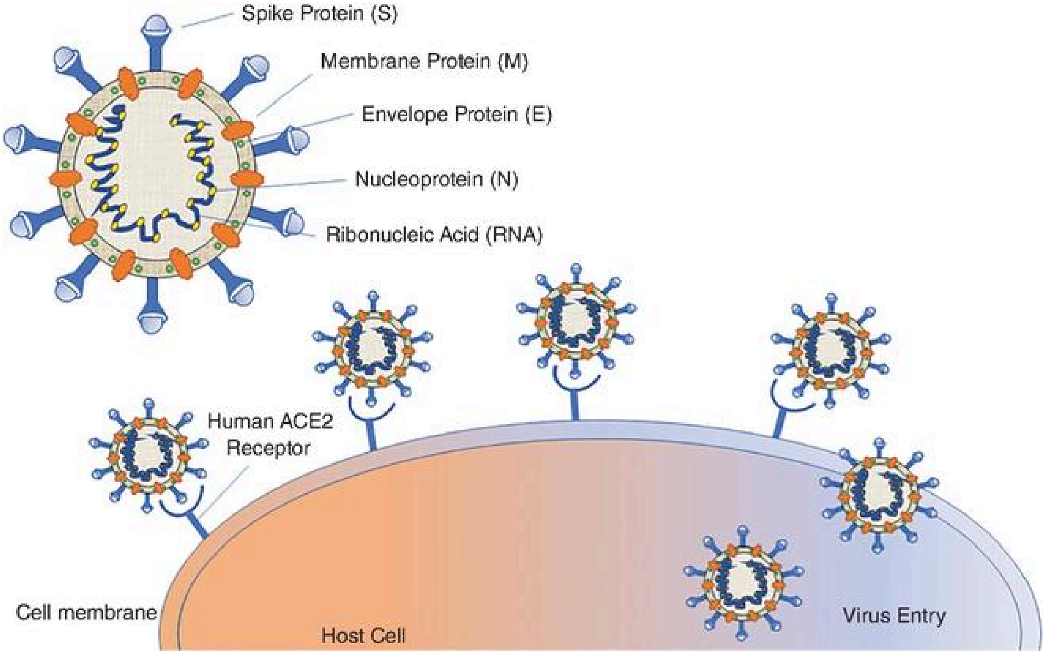
Introduction

By July 2023, 768 million people had been diagnosed with COVID-19, and circa seven million had died.[1] In the 2 years to January 2022, about 16% of hospitalised patients developed critical illness,[2] although vaccination now limits the number of hospitalised[3,4] and disease severity,[5] and treatments limit progression. Indeed, for every 100,000 people in England in early 2023, 10.62 were hospitalised but only 0.28 were admitted to an intensive care unit (ICU).[6] This chapter summarises key aspects of COVID-19 pathophysiology, diagnosis and pharmacotherapy. Quality data regarding clinical management are scant, with much critical care based on experience of other conditions and expert consensus.

Aetiology and Pathogenesis

SARS-CoV-2 Virus and Mechanism of Entry

SARS-CoV-2 is an enveloped respiratory droplet-transmitted RNA β-coronavirus.[7,8] Attachment of the viral spike (S) protein's receptor-binding domain (RBD) to cell surface angiotensin-converting enzyme 2 (ACE2) receptors (widely somatically distributed, but abundant on respiratory endothelium[9]) mediates cell entry (Fig. 49.1), although alternative mechanisms exist.[10] Infected people are most contagious during days 7–10 when the upper respiratory tract (URT) viral load is highest. Prolonged viral RNA shedding can occur, but is generally not considered indicative of prolonged infectiousness.[11]



Spike Protein (S)
Membrane Protein (M)
Envelope Protein (E)
Nucleoprotein (N)
Ribonucleic Acid (RNA)
Human ACE2 Receptor
Cell membrane
Host Cell
Virus Entry

The diagram presents the viral structure of Severe Acute Respiratory Syndrome Coronavirus Two. The labelled parts of the virus are spike protein, membrane protein, envelope protein, nucleoprotein, and ribonucleic acid or R N A. The virus attaches itself to the human A C E 2 receptor on the cell membrane of a host cell, breaching the membrane and entering into the cell.

FIG. 49.1 SARS-CoV-2 viral structure and cellular entry. From Naqvi AAT, Fatima K, Mohammad T, et al. Insights into {SARS}-{CoV}-2 genome, structure, evolution, pathogenesis and therapies: {Structural} genomics approach. *Biochim Biophys Acta Mol Basis Dis* . 2020;1866(10):165878. https://doi.org/10.1016/j.bbadis.2020.165878 .

Inflammation in Pathogenesis

SARS-CoV-2 infection causes COVID-19 disease, characterised by hyperinflammation/cytokine release (e.g. IL-6 and interferon-alpha).[12] Cellular injury through activation of the immune system and the alternative complement pathway by the spike protein, supplements that from infected cell lysis.[13], [14] A multifactorial procoagulant state[15–17] causes micro- (and macro-) thromboses, contributing to organ injury.

SARS-CoV-2 Variants

Since its emergence, new SARS-CoV-2 variants of concern (VOCs) have developed through mutation and natural selection. The World Health Organisation (WHO) designates the most prevalent using the Greek alphabet.[18] Alpha was <75% as transmissible as the original wild-type, and Delta more so, with a higher risk of severe disease.[19], [20] Now globally dominant (August 2023), many Omicron sublineages exhibit greater immune evasion and re-infection risk, but lesser disease severity.[20–22]

Immunity

Most of the infected develop detectable nucleocapsid (N) and spike protein (S) RBD serum antibodies (Fig. 49.1). CD4 T-cells support this humoral immune response, driving CD8 T-cell killing of infected cells.[23] Immune response magnitude may be related to initial disease severity and ‘Long Covid’ risk. Until Omicron’s emergence, prior infection reduced re-infection risk by <80%.[24] Vaccines protect well against severe disease,[25] although less against symptomatic Omicron infection.[26]

Epidemiology

Outcomes for Different Waves

Globally, <20% of those infected in the initial pandemic phase (‘wave 1’) required hospitalisation, of which 25% required CCU admission and 2%–

20% died.[27–29] However, geographically limited and variable access to testing, clinical resource and hospital/CCU admission criteria constrained data interpretation. Global data, still incomplete, suggest substantially reduced admission (with new variant emergence, survivor bias and immunity via infection or vaccination and application of new therapeutics), and case fatality rates (<0.3%).[30] In July 2023, European Union COVID-19-related hospital admission and CCU-bed occupancy were 0.6–0.1/100,000 respectively, with 0.94% US hospital and 0.86% CCU-bed occupancy.[31], [32]

Risk Factors for Severe Disease

Of multiple risk factors for severe COVID-19 disease (Table 49.1), age is the strongest. During wave 1, death risk was 340-fold higher for ages >85 versus 18–29 years.[33], [34] This gradient has declined, partly with age-based eligibility vaccination criteria in many countries. Younger patients with severe disease are more likely to be male and to have co-morbidities which correlate with disease severity.[35] Ethnicity associations reflect socioeconomic health determinants (e.g. occupation-related viral exposure and access to healthcare) and genetic factors.[36–40] Mortality rates are 14-fold higher for unvaccinated versus fully vaccinated individuals.[25], [41] Tools to identify risk of severe disease are insufficiently validated for widespread clinical use.[42]

Table 49.1

Risk factors for severe COVID-19 disease

Asthma

Active solid organ and haematological malignancies

Cardiovascular disease – heart failure, coronary artery disease, cardiomyopathies

Cerebrovascular disease

Chronic kidney disease

Chronic lung diseases – bronchiectasis, chronic obstructive pulmonary disease, interstitial lung disease, pulmonary arterial hypertension

Chronic liver diseases – cirrhosis, non-alcoholic fatty liver disease, alcoholic liver disease, autoimmune hepatitis

Cystic fibrosis

Dementia

Diabetes mellitus – type 1 and type 2

Disabilities – congenital and acquired

Human immunodeficiency virus (HIV) infection

Immunosuppression, including use of systemic corticosteroids

Mental health disorders – depression and schizophrenia

Obesity – body mass index $>30\ \mathrm{kg/m}^2$

Physical inactivity

Pregnancy and recent pregnancy

Primary immunodeficiences

Smoking – current and former

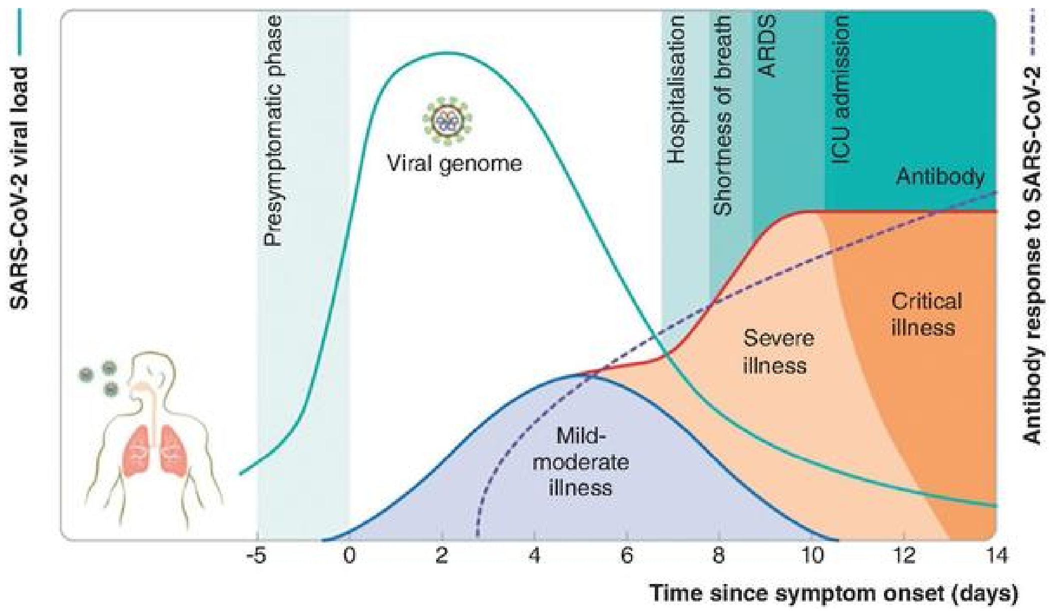
Solid organ or stem cell transplant
Tuberculosis

Adapted from Centers for Disease Control and Prevention. [198]

Assessment and Diagnosis

Clinical Manifestations

Most COVID-19 patients have non-specific systemic symptoms (e.g. fever and myalgia). [43], [44] Anosmia now affects about 20% of symptomatic cases. [43] Unvaccinated individuals more commonly report fever. [45] Cough, often non-productive, remains the predominant symptom (>50% of patients), although Omicron is associated with predominantly URT symptoms and a relative reduction in incidence of cough and dyspnoea. [46], [47] The elderly and immunosuppressed are more likely to be afebrile, or suffer atypical and non-localising features. [44] Fig. 49.2 displays symptom development against viral load/ time.



The graph presents the progression of Severe Acute Respiratory Syndrome Coronavirus Two infection over a timeline of fourteen days since symptom onset. The horizontal axis represents time in days, which ranges from negative five to fourteen. The vertical axis on the left side is labelled Severe Acute Respiratory Syndrome Coronavirus Two viral genome, and the vertical axis on the right side is labelled antibody response to Severe Acute Respiratory Syndrome Coronavirus Two. Two curves are plotted. The first curve, labelled viral genome, peaks around day zero and declines by day ten. The second curve, labelled antibody, starts around day two, peaks around day eight, and rises steadily through day fourteen. Shaded regions mark phases of illness. From day two to day ten, a region is labelled mild-moderate illness. From day eight to day thirteen, a region is labelled severe illness, and from day twelve, it is labelled critical illness. The graph is further divided into the following sections. Day negative five to 0:

presymptomatic phase, day 0 to day 6: where the viral genome peaks, day seven to day eight: hospitalisation, day eight to day nine: shortness of breath, day nine to day ten: A R D S, day ten to day fourteen: I C U admission.

FIG. 49.2 Viral load and symptom development in acute SARS-CoV-2 infection. Adapted from Oberfeld B, Achanta A, Carpenter K, et al. SnapShot: COVID-19. Cell. 2020;181(4):954-954.e1, ISSN 0092-8674, https://doi.org/10.1016/j.cell.2020.04.013 .

Current data on organ-specific manifestations are limited. Unless otherwise stated, data below refer to wave 1 (the wild-type virus). However, patterns have changed with viral evolution, vaccination and immunity, survivor bias and new therapeutics.

Lung Injury

Pneumonitis remains the commonest COVID-19 manifestation: dyspnoea develops within (median) 5-days of symptom onset; lung involvement severity peaks at 10-12 days.[7,48] Alveolar-capillary barrier injury is akin to classical acute respiratory distress syndrome (ARDS), with the development of hyaline membranes.[49,50] Diffuse pulmonary endothelialitis and vascular microthrombosis attenuate pulmonary hypoxic vasoconstriction, causing profound ventilation-perfusion mismatching[51] and acute hypoxaemic respiratory failure (AHRF).

ARDS occurred in approximately 30% of hospitalised COVID-19 cases, and 75% of CCU admissions: 12%–24% of these required invasive mechanical ventilation (IMV) but fewer now for reasons outlined above.[27–29,52] Pneumothorax/pneumomediastinum (spontaneous or secondary to IMV barotrauma) is associated with higher mortality.[53,54]

Cardiac Dysfunction and Arrhythmia

In wave 1, serum cardiac troponin >99th percentile occurred in 21%–50% of patients (especially those aged >70 years).[55,56] Although myocarditis affected <27.8% of patients,[57] the incidence has declined to 2.4/1000 admissions (manifesting most commonly as fulminant heart failure).[58] Pericarditis and diverse arrhythmias occur (new-onset atrial fibrillation originally affecting 11%, and ventricular arrhythmias <10% of hospitalised patients).[55,59,60] Hypotension results from systemic vasodilatation, sedation-related reduced sympathetic drive and hypovolaemia (high insensible losses and reduced fluid intake).

Acute Kidney Injury (AKI)

AKI affected >20% of hospitals and 50% of CCU admissions,[61] likely driven by insensible fluid losses, viral renal cytopathy, rhabdomyolysis, microthrombosis and (in wave 1) fluid-restrictive management strategies,[61–63] and independently predicts COVID-19 CCU admission/mortality.[64] Risk factors are conventional. Requirement for renal replacement therapy (RRT) has declined[65] from 27.5% (UK wave 1) to 14.3% (wave 2), and in the US 6% (Delta) to 1% (Omicron).[52]

Neurological

Encephalopathy originally affected 8%–12% of hospitalised patients.[66] Delirium (<50%) was associated with a 3-fold higher mortality rate in patients >65 years.[67,68] Seizures can occur.[69] Less common neurological involvement includes meningoencephalitis and posterior reversible encephalopathy syndrome in association with hypertension and renal failure.[70,71] Abnormal magnetic resonance imaging occurs in <50% of patients with neurological symptoms, and cerebrospinal fluid analysis is often inconclusive.[72,73] Stroke prevalence has reduced, although data regarding the changing incidence of other neurological presentations are sparse.

Haematological

Haematological manifestations have evolved. Venous thromboembolism (VTE) affected <40% of hospitalised patients in wave 1, but 8% (23% of ICU admissions) by 2023. [74, 75] Risk factors are similar to those in non-COVID-19 patients. Arterial thrombosis is less common. Stroke incidence (predominantly ischaemic) declined from 11% of hospital admissions (wave 1) to <3%. [66, 68] Immune thrombocytopaenia is recognised, but major bleeding is rare in the absence of anticoagulation. [76, 77]

Investigations

Diagnosis of SARS-CoV-2 infection requires RNA reverse transcriptase-polymerase chain reaction (RT-PCR) testing of URT samples. Sputum/deep tracheal aspirate sample analysis (microscopy and culture), respiratory viral RNA ((para)influenza, metapneumo-/adeno-/rhino-/entero-/parecho-virus) and *Legionella pneumophila* and *Mycoplasma pneumoniae* co-infection are often routinely sought, and *Mycobacterium tuberculosis* were clinically indicated. Likewise, serum beta-D-glucan and galactomannan antigen testing given the risk of invasive fungal infection after immunosuppressive therapy.

The utility/limitations of inflammatory markers (e.g. white cell count (WCC), C-reactive protein (CRP), procalcitonin (PCT) and low neutrophil-lymphocyte ratio (NLR)) to diagnose and monitor bacterial infection are discussed later. Other laboratory findings associated with COVID-19 (and its severity) are elevated D-dimer, ferritin, creatine kinase (CK), high sensitivity troponin T or I, N-terminal pro-B-type natriuretic peptide and interleukins 6 and 10 (IL-6 and IL-10). [76, 77]

Chest radiographs typically show patchy pulmonary infiltrates ± pneumothorax/pneumomediastinum. Chest computer tomography (CT) findings with the highest specificity are peripheral (subpleural) ground glass opacification and bronchovascular thickening [78] and, furthermore, CT can help identify pulmonary thromboembolic disease.

Management

COVID-19 Specific Treatment

Non-invasive respiratory support (NIRS) refers to the use of high-flow nasal oxygenation (HFNO, a humidified blended air/oxygen mixture at ≤60 L/min), continuous positive airway pressure (CPAP, typically 5–12 cmH_2O) and bi-level positive airway pressure (BiPAP). CPAP and BiPAP are often referred to as non-invasive ventilation (NIV).

Treatment is generally determined by disease severity.[79] Severe disease is defined by AHRF (SpO_2 <90%) requiring supplementary oxygen, respiratory rate (RR) >30 breaths/minute or evidence of respiratory distress. Critical disease is defined as patients who require NIRS and/or other organ support. Recommended management is based on six international guidelines (Box 49.1).[79–84]

NICE , National Institute for Clinical Excellence (UK); *NIH* , National Institutes of Health (US); *WHO* , World Health Organisation.

Systemic Corticosteroids

These are recommended for ‘severe’ and ‘critical’ COVID-19 (WHO criteria above) based on meta-analysis of randomised controlled trials (RCTs) (7 recruiting only patients with critical illness, one recruiting only patients with severe illness and one moderate-to-critical illness) by the UK National Institute for Health and Care Excellence (NICE). [80] Typical doses (dexamethasone 6 mg o.d., or hydrocortisone 50 mg q.d.s., for <10 days) are based on the RECOVERY trial, where treatment reduced 28-day mortality (rate ratio 0.83; 95% CI: 0.75–0.93). [85] Corticosteroids reduced all-cause mortality (relative risk (RR) 0.84; 95% CI 0.73–0.98) and IMV rates (RR 0.88, 95% CI 0.79–0.97), without increased risk of gastrointestinal bleeding, bacterial co-infection, hyperglycaemia or neuromuscular weakness. [86] A retrospective ‘real world’ study (1100 UK patients) was supportive: steroids for >3 days reduced mortality in severe/critical illness (HR 0.47; 95% CI: 0.31–0.72). [87] Although disputed, [88] , [89] the NICE recommendation is supported by five other international guidelines. [79] , [81–84]

Other Immunomodulators

Inhibitors of interleukin-6 (monoclonal antibody Tocilizumab) or Janus kinase-1&2 (JAK-1&2) (baricitinib), are recommended adjuncts to systemic corticosteroids in severe or critical COVID-19. [85] , [90–93]

Tocilizumab (60-minute infusion of 400–800 mg) [79–84] inhibits the IL6/sIL6 receptor complex binding to alveolar epithelial cells. In a retrospective analysis (3942 patients), tocilizumab within 2 days of CCU admission lowered mortality (HR 0.71; 95% CI 0.56-0.92).[94] Most patients received no corticosteroids (357/491), suggesting independent benefit. In the COVACTA RCT (mainly CCU patients: 301/438), tocilizumab reduced duration of supplemental oxygen use and time to clinical improvement (National Early Warning-2 score of ≤ 2 for 24 hours).[95] In REMAP-CAP trial patients (71% required NIV or IMV, and 19% vasopressors), tocilizumab superiority – (more organ support free days (aOR 1.64; 95% credible interval, 1.25–2.14) and increased survival (aOR 1.64; 95% credible interval, 1.14–2.35)) – persisted irrespective of the baseline CRP. The WHO's review of 30 RCTs (10,618 patients) confirmed tociluzimab's benefit when used alone, with possible corticosteroid synergistic benefit.[79, 96, 97] Tocilizumab is contraindicated in neutropaenia ($<1 \times 10^{9}$/L), thrombocytopaenia (platelets $<50 \times 10^{3}$/microlitre) or if hepatic enzymes are 10 × upper limit of normal.[98]

Baricitinib (4 mg daily orally in adults with eGFR $\geq$ 60 mL/min/1.73 m^{2} for 14 days or until hospital discharge) is a (cytokine-response modifying) JAK 1/2 inhibitor.[99] Some evidence suggests that it reduces mortality in critical COVID-19. An exploratory RCT (101 patients receiving IMV or extra corporeal membrane oxygenation (ECMO), part of the COV-BARRIER study) reported a reduction in 60-day mortality (HR 0.54; 95% CI 0.31–0.96; absolute risk reduction 19%), but no difference in ventilator-free days or hospitalisation duration.[100] In the ACTT-2 study, 55%, 21% and 11% of patients received conventional oxygen therapy (COT), NIRS and IMV/ECMO, respectively. Baricitinib with Remdesevir (vs Remdesevir alone) improved 28-day mortality (5.1% versus 7.8%; HR for death, 0.65; 95% CI, 0.39–1.09),[101] and the COV-BARRIER study of less severe illness (63% and 24% receiving COT and NIRS, respectively), confirmed outcome benefit.[102] Overall, analysis of 4 RCTs suggests that Baricitinib reduces mortality and progression to IMV (moderate certainty, due to trial heterogeneity).[79, 80, 84] Baricitinib is contraindicated in neutropaenia ($<1 \times 10^{9}$/L), lymphopaenia ($<0.5 \times 10^{9}$/L), haemoglobin <80 g/L or the presence of active tuberculosis.[98]

RCT meta-analysis reports no significant increase in adverse events with IL-6 receptor or JAK inhibitors. However, because immunomodulators can increase risk of opportunistic infection and reactivation of latent TB, use of only one (added to a corticosteroid) is recommended by all international guidelines, although the WHO suggest that a corticosteroid, IL-6 inhibitor and baricitinib can be considered in combination for severe or critical illness. [79]

The key clinical trials of novel pharmacotherapy for COVID-19 are provided in Table 49.2 and Box 49.2 summarises the recommended regimens based on disease severity.

Table 49.2

CI , Confidence interval; *HFNO* , high-flow nasal oxygen; *HR* , hazard ratio; *ICU* , intensive care unit; *IL-6* , interleukin-6; *IMV* , invasive mechanical ventilation; *JAK* , Janus kinase; *NIV* , non-invasive ventilation.

Box 49.2

COVID-19 Specific Treatment Summary

- Moderate COVID-19 + no oxygen:
  - 1st line: Nirmatrelvir plus ritonavir (Paxlovid)
  - 2nd line: Consider: Remdesevir, Molnupiravir or Sotrovimab
- **Severe COVID-19: oxygen only**
  - Dexamethasone ± Remdesevir
- **Critical COVID-19: NIRS or oxygen + other organ support**
  - Dexamethasone + Tolicizumab or Baricitinib

NIRS, Non-invasive respiratory support .

Antiviral Therapy

Used early, this can mitigate progression to severe disease and the need for hospitalisation in high-risk individuals. [101–103] For patients not requiring oxygen or NIV, with ≥1 risk factor for severe disease, nirmatrelvir plus ritonavir (Paxlovid) is recommended first line treatment, with Sotrovimab as second line [104] (UK). Other guidelines suggest Remdesevir or Molnupiravir as alternatives. [105]

Remdesevir was licensed early to treat COVID-19. [106] The large ‘Solidarity’ RCT and accompanying meta-analysis of 7 RCTs show a modest reduction in mortality and progression to IMV with Remdesevir treatment of moderate-severe illness. [107] Most guidelines recommend that Remdesevir be considered for ≥5 days in those requiring oxygen (<15 L/min), but not NIV or IMV. [79], [80], [84] However others suggest that certain NIRS-treated subgroups may benefit (the immunocompromised, evidence of ongoing viral replication) if given within 10 days of symptom onset. [83], [108]

Antimicrobial Therapy

Bacterial co-infection is uncommon at presentation: of 18,376 respiratory tract culture samples from hospitalised cases, 1140 (6%) had a clinically significant bacterial pathogen within 7 days of admission. [109] Prophylactic antimicrobial therapies are thus not recommended in severe or critical COVID-19. [80], [83], [84] Careful surveillance for secondary infection and robust antimicrobial multidisciplinary stewardship is recommended, as bacterial co-infection worsen outcomes. [109], [110]

Traditional markers (e.g. fever and inflammatory markers) to detect/monitor bacterial infection are imperfect: COVID-19 can cause persistently elevated CRP and WCC (days–weeks); corticosteroids cause leucocytosis or leucopaenia, and immunomodulatory drugs suppress CRP. PCT level on hospital admission may not reliably indicate bacterial infection. [111] In CCU, positive respiratory samples are more frequent (42.1% in sputum, 51.5% for deep samples), but blood cultures are less so (8.1% positivity rate). [112] Obtaining high-quality samples when bacterial co-infection is suspected, is thus essential.

Ventilatory Support

Respiratory Support

NIV, not routinely applied in hospitalised pneumonia,[113–115] was extensively used to treat COVID-19 pneumonitis. HFNO provides PEEP of ≤ 6 cmH$_2$O,[116] facilitates eating, drinking and talking, and was used as a sole intervention or to allow 'breaks' from NIV use. Both modalities improve oxygenation and reduce the work of breathing. Higher transpulmonary pressures in NIV improve lung recruitment[117] but HFNO can be easier to apply, better tolerated and may perform similarly to NIV in non-hypercapnoeic COVID-19 AHRF.[118] However, a meta-analysis of 17 non-COVID-19 studies suggests lower IMV rates when NIV is used to treat AHRF, compared to COT or HFNO.[119]

There are risks associated with both modalities. Any form of NIRS may mask clinical deterioration and delay IMV.[120] HFNO precludes end-tidal CO$_2$ or pulmonary pressure/volume measurement. NIV, and to a lesser extent HFNO, have been implicated in inducing patient self-inflicted lung injury (P-SILI) in COVID-19 AHRF through prolonged high minute ventilation, large pleural pressure swings, increased regional lung stress/strain, non-homogenous distribution of ventilation, alterations in lung perfusion and NIV-patient dysynchrony.[121] Barotrauma (pneumothrorax/pneumomediatinum) may result.[122], [123] Finally, aerosolisation risk from NIRS remains unclear. All guidelines recommend that healthcare workers wear an FFP-3 or N-95 facemask, and most full personal protective equipment (PPE) with or without negative pressure isolation.[124]

Wave 1 evidence suggested that NIV may be superior to COT and HFNO in COVID-19 AHRF requiring a FiO$_2$ >0.4 or having a PaO$_2$/FiO$_2$ ratio <125 mm Hg, and was associated with lower IMV rates and more IMV-free days.[125–127] However, the largest contributing RCT (1278 patients), RECOVERY-RS,[128] was criticised for treatment-group crossover and possible underpowering to detect differences between COT and HFNO. Indeed, two subsequent RCTs found that HFNO was superior to COT (IMV use and time to recovery).[129, 130] Furthermore, an RCT comparing long-term outcomes of HFNO versus NIV found no difference in lung function, physical performance or quality of life at 6 months, although (unsurprisingly) functional outcomes for patients later receiving IMV, were worse.[131] Six meta-analyses (January–December 2022) suggest that IMV and mortality rates were lower with NIRS than COT, with data comparing HFNO and NIV conflicting and inconclusive. Given this uncertainty, guidelines conflict: first-line therapy is variably considered to be HFNO (European Society of Intensive Medicine, and Society of Critical Care Medicine); CPAP (Italian Association of Hospital Pulmonologists and Australian Guidelines for the Clinical Care of People with COVID-19); and either HFNO or CPAP (Joint British Thoracic Society, UK Intensive Care Society guidelines and World Health organisation, among others).[82–84, 120, 132]

In general, any hospitalised COVID-19 patient requiring FiO_2 >0.4 should be discussed with local CCU services and considered for escalated respiratory support and/or transfer to a CCU environment. Pulse oximetry (SpO_2) can be inaccurate due to peripheral hypoperfusion and/or skin pigmentation, resulting in delayed intubation and poorer outcomes.[133] NIRS patients should be monitored carefully to minimise delays in escalation to IMV. A ratio of oxygen saturation to respiratory rate (ROX index) >4.8 and a HARCOR index (heart rate, acidosis, consciousness, oxygenation and RR) >5 at 12 hours from commencement may identify HFNO and NIV failure, respectively,[121, 133] and aid clinical decision-making.

Awake Prone Position Ventilation (APPV)

In spontaneously breathing patients, lying prone for 1–16 hours/day[134] (±NIRS) improves ventilation-perfusion matching, homogeneity of lung stress and strain, and oxygenation[135] and (five meta-analyses) reduces IMV rates (those receiving HFNO or NIV benefiting most), but with no difference in mortality or other outcomes).[134, 136–139] The most recent meta-analysis (17 trials, 2931 patients) reported reduced IMV rates (RR 0.83, 95% confidence interval 0.73 to 0.94), equivalent to 55 fewer intubations per 1000 patients. However, no significant difference was observed in mortality, escalation of oxygen modality, hospital or ICU length of stay (LoS) or ventilator-free days.[136] Adverse events are few. APPV should be considered in those requiring COT or NIRS, in the absence of any contraindication.

Invasive Mechanical Ventilation

Early COVID-19 pneumonitis is characterised by preserved lung compliance. Whilst guidelines[84] suggest considering IMV in patients receiving HFNO or NIV with FiO_2 >0.4 and SpO_2 <92% (or <88% if at risk of hypercapnoea), the decision is clinical and patient-specific (e.g. considering co-morbidities, functional status and patient wishes). Optimal intubation timing is not known. Data suggesting that delayed intubation (>48 hours) may be associated with higher mortality,[140,141] are inconclusive, with evidence (above) that NIRS may delay or obviate the need for IMV.

Standard ARDS management should be employed, modified by local policies and resources.[142,143] In general, conventional lung protective ventilation (LPV) should be used (tidal volumes 6–8 mL/kg, driving pressure <15 cmH_2O, plateau pressure <30 cmH_2O). Optimal (compliance-based) PEEP should be applied, noting that early lung compliance is usually good and high PEEP unnecessary/harmful. Current guidance advises against *routine* early use of continuous neuromuscular blockade (NMB) in ARDS unless sedation depth is optimised. If LPV targets are still not achieved in moderate to severe ARDS, NMB can be considered for 48 hours.[144,145] However, there are no specific recommendations for/against NMB use in COVID-19, with use guided by clinical judgement.[146,147]

Airway pressure release ventilation (APRV) may minimise derecruitment, improve oxygenation and limit peak airway pressures,[148] although outcome benefits are unproven. APRV and recruitment manoeuvres are discouraged when low lung compliance (later ARDS), hypovolaemia, haemodynamic instability or severe pulmonary hypertension exist. No evidence supports corticosteroid use beyond the 10-day course for

COVID-19, unless there is steroid-responsive lung pathology (e.g. pneumocystis jirovecii or acute eosinophilic pneumonia).

Prone positioning in IMV with moderate-severe ARDS (PaO_2/FiO_2 ratio <150 mm Hg) for >12–16 h improved oxygenation and reduced mortality in the PROSEVA RCT, and in subsequent meta-analysis of 7 trials.[149, 150] It requires an adequate number of trained staff to protect against skin, eye, mouth or nerve injury, and tube and line positions. The head should be turned and arm positions changed regularly (e.g. every 3 hours) to mitigate these complications.[81] Proning teams may improve efficiency, particularly where large numbers require proning.[135]

Complications of IMV in COVID-19 were generally similar to other forms of ARDS, but some were unique. Saturation and obstruction of heat-moisture exchange filters were not uncommon, causing sudden, progressive deterioration in minute ventilation and rise in airway pressure; rates of ventilator-associated pneumonia were higher in COVID-19; barotrauma in COVID-19 may be influenced by P-SILI prior to initiation of IMV. Tracheal complications were widely reported in wave 1 IMV patients, including full-thickness tracheal lesions or tracheoesophageal fistulae, perhaps due to interplay between prone positioning, prothrombotic phenomena and microvascular ischaemia.[151]

Extracorporeal Membrane Oxygenation (ECMO)

This may be considered in COVID-19 AHRF, where conventional ventilatory support therapies are exhausted.[152, 153] VV-ECMO remains the most prevalent form (<96% of cases).[154, 155] Mechanical circulatory support use (e.g. veno-arterial ECMO, Impella device or an intra-aortic balloon pump) was infrequent, and outcome data are scarce.[155]

Evidence that ECMO benefitted non-COVID-19 ARDS was inconclusive,[156–159] with early COVID-19 observational studies reported similar outcomes.[154, 160, 161] ECMO mortality rose later in the pandemic data[162, 163] (37.1%,[164] 39%[165] and 54% in recent meta-analyses),[166] perhaps with the effect of more virulent VOCs, wider immunosuppression use, or longer duration of NIRS before commencing ECMO. COVID-19 ECMO patients also have a greater prevalence of right ventricular failure, and need for anticoagulation (higher incidence of macro- and microvascular thromboses) which in turn resulted in high bleeding complication rates [167] (31%). [168] Other complications are common (74% overall): neurological (stroke and intracranial bleeding) (32%), gastrointestinal (e.g. bleeding or bowel ischaemia) (23%) or need for RRT (23%). A >4-day gap from intubation to commencing ECMO is associated with higher in-hospital mortality. [168]

In a recent meta-analysis (42 studies; 17,449 patients treated with ECMO for COVID-19), independent mortality predictors included age, male sex, chronic lung disease; markers of lung injury severity (e.g. prolonged disease course or duration of IMV, higher driving pressure or partial pressure of arterial CO_2) and the ECMO centre's level of experience. [166]

Given high mortality and complication rates and that ECMO is resource-intensive with limited availability, ECMO referral should be timely, carefully considered, and based on careful patient selection using national guidelines and local policy.

Role of Tracheostomy

Tracheostomies help reduce IMV duration and sedation, ventilator-associated complications and ICU LoS. [169] Reported tracheostomy rates in IMV COVID-19 were 16%–61%. [170] A recent large systematic review reported that tracheostomy <7days in non-COVID IMV patients may be associated with fewer complications and lower mortality. [171] However, meta-analysis of relevant studies in COVID-19 [172–174] showed a pooled mortality of 19%–38%, time to decannulation of 17–21 days and IMV duration of 23.4–24.1 days (outcomes similar to those in non-COVID-19 ARDS) and no difference in outcome between early versus late tracheostomy, or percutaneous versus surgical insertion. [175] Complication rates varied from 14.4%–40%, with possibly being significantly higher with surgical tracheostomy. [173]

Cardiovascular Support

Circulatory shock in COVID-19 should be assessed and managed according to standard practice.[82] Conservative fluid management (to reduce extravascular lung water) risks intravascular depletion, with hypotension exacerbated by systemic vasodilatation[176,177] responsive to norepinephrine. As high dose norepinephrine (>0.5 mcg/kg/min) may increase pulmonary vascular resistance (PVR), early consideration of vasopressin may be prudent, given its preferential activity on systemic vasculature at low doses (≤0.03 units/kg/min).[178]

Impaired cardiac function must also be sought (LV and RV dysfunction is not uncommon[179]) and can be conventionally managed.[83] Levosimendan improves pulmonary artery/RV coupling and reduces PVR without increasing myocardial oxygen consumption,[180] although prospective trial data for COVID-19 are lacking. Inhaled nitric oxide (5–40 parts per million) may have advantages in treating *cor pulmonale* and RV dysfunction secondary to COVID-19 ARDS, although outcome benefit has not been proven.[181]

Renal Management

Renal dysfunction is not uncommon in COVID-19 (see previously). Oliguria is common (75%) but not necessarily associated with poorer outcomes, and serum creatinine AKI criteria are often not met. As such, oliguria may represent a temporary functional change rather than structural damage.[182] Standard risk minimisation methods and management (including RRT indications) should be utilised. Medical management (e.g. loop diuretics, potassium binders and sodium bicarbonate) may avoid the need for RRT in some, sparing resources during overwhelming pandemic surges.[183] Need for RRT was associated with a higher COVID-19 mortality and, as for non-COVID-19 data, without difference between early and delayed RRT.[182,184–186] Of note, tocilizumab reduced the need for RRT in critically ill patients.[187]

Anticoagulation and Anti-Platelet Therapy

All patients require VTE risk assessment. For patients requiring COT, HFNO, NIV or IMV a standard prophylactic dose of low molecular weight heparin (LMWH) should be prescribed within 14 hours of admission. Some guidelines support use of higher doses, although this is not universally accepted.[80, 81, 83, 84] If eGFR is <30 mL/min/1.73 m^2, unfractionated heparin or clearance-adjusted doses of LMWH may be used.

Practical Considerations for COVID-19 Management

Aerosol-generating procedures

Risk of viral transmission to healthcare workers rises the greater the concentration of particles aerosolised from the respiratory mucosa, in early severe disease (with higher viral load), and with greater proximity and duration of exposure.[188] There is no international consensus about which aerosol-generating procedures (AGPs) are high-risk. The WHO list (cardiopulmonary resuscitation, intubation, NIV, bronchoscopy, tracheostomy insertion and tube change and sputum induction[189]) is contested: The UK Infection Control and Prevention group’s systematic review suggests that intubation, extubation, manual face mask ventilation and NIV be removed.[190, 191] Nevertheless, if aerosol exposure risk exists, PPE, including a filtering face piece-3 (FFP-3) or equivalent mask, gloves and a visor should be worn. Guidelines concerning the need for body protection vary: UK government guidance advices that wearing an apron is adequate,[190] however, others recommend wearing a water-repellent gown.[192, 193] Additionally, it has been suggested that AGPs should ideally be performed in negative pressure rooms.[82]

Cardiac arrest in the prone position

The American Heart Association recommends that patients receiving HFNO or NIV and prone should be rendered supine as soon as possible if cardiopulmonary resuscitation (CPR) is required. In IMV, chest compressions and defibrillation can be attempted prone if supination is not immediately practical or safe.[194] Prone CPR with sternal counter-pressure is as effective as supine CPR in terms of the arterial blood pressure generated and survival rates. [195] Invasive blood pressure monitoring and end-tidal CO_2 may help assess the optimum time to revert to the supine position. [84]

Treatment escalation decisions

Where surges in the number of critically ill patients strain resource, challenging decision-making about escalating care intensity, [196] a shared decision-making process involving the patient, senior referring doctor and critical care team should be used. [197] If a patient lacks mental capacity, their wishes and beliefs should be determined by consulting their next of kin or an independent mental capacity advocate (IMCA). Scoring systems such as the Clinical Frailty Score (CFS) or 4C Mortality Score may help inform discussions.

Extracorporeal membrane oxygenation for respiratory failure

Vince Pellegrino, Brooke Riley and Julia Coull

ECMO for Respiratory Failure

The management of severe respiratory failure and avoidance of lung injury remains a significant problem in critically ill patients. Despite the use of protective mechanical lung ventilation, the mortality of patients with severe acute respiratory distress syndrome (ARDS) remains high and increases with the severity of lung injury. [1] Protective lung ventilation in patients with severe ARDS may be limited by progressive hypoxaemia and hypercapnia despite recourse to adjunctive therapies that improve oxygenation, such as inhaled nitric oxide (NO) or prone positioning.

Veno-venous extracorporeal membrane oxygenation (V-V ECMO) and veno-pulmonary (V-PA ECMO) are alternative forms of lung support that provide *non-pulmonary oxygen delivery and carbon dioxide removal* , facilitate lung protective ventilation and allow time for lung recovery. [2] Modern ECMO systems can be instituted rapidly and non-surgically, their compact size facilitates inter-hospital patient transport even over long distances, and they are able to provide support over days to months. The use of V-V ECMO increased during recent respiratory viral pandemics and survival benefit in adults with severe ARDS has been widely accepted. [3, 4] Outside pandemics, the use of respiratory ECMO support is low and ECMO care should be provided by speciality centres.

Definitions: Extracorporeal Membrane Oxygenation (ECMO)

This is a form of extracorporeal support comprising a specialised *access cannula* to drain venous blood, an external circuit (*tubing*), a gas exchange device (*oxygenator*) where blood becomes enriched with oxygen (O_2) and has carbon dioxide (CO_2) removed, and a *return cannula* through which circuit blood returns to the patient. A pump drives the circuit blood flow and heat exchange is possible. A *FGF* is delivered to the oxygenator. ECMO can provide adequate oxygenation and CO_2 clearance in patients with minimal or absent native lung function. ECMO may achieve fully oxygenated circuit blood flows up to approximately 7 litres of blood per minute.

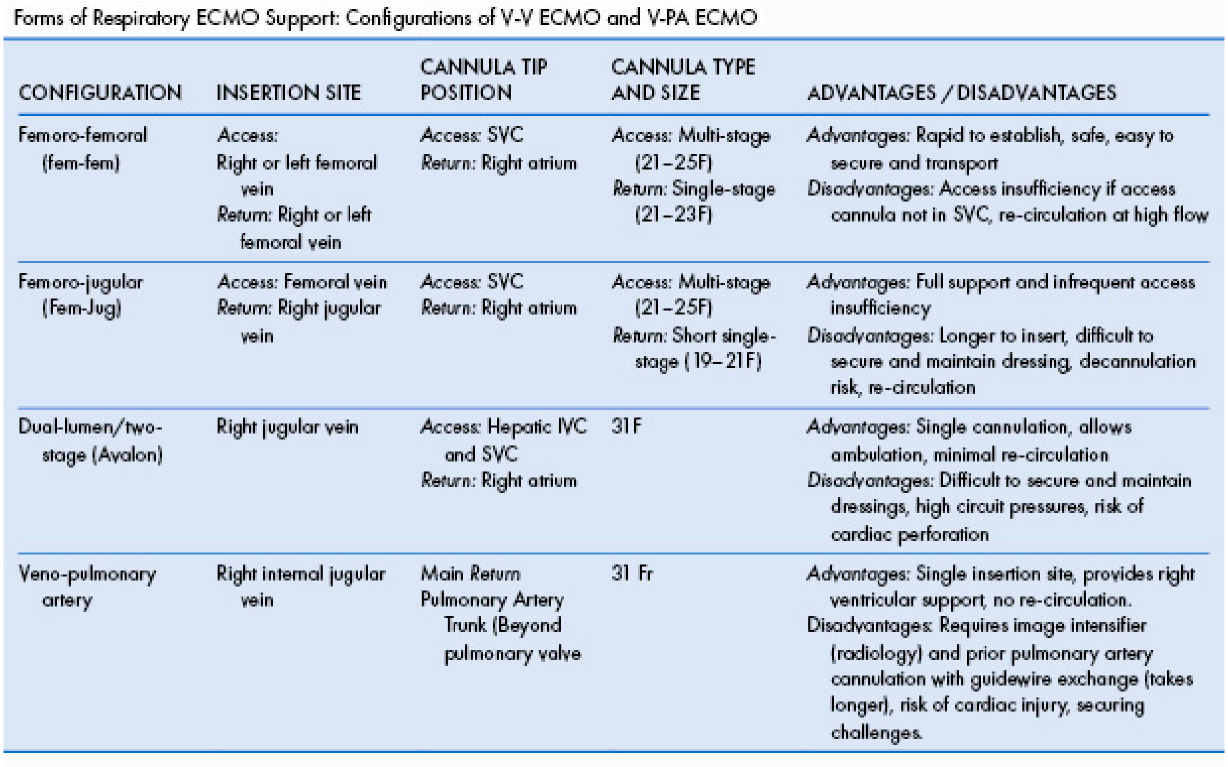
Mode

The vessels from which ECMO circuit blood is obtained and returned define the *mode of ECMO* . Veno-venous ECMO (V-V ECMO) is the predominant ECMO mode used for respiratory support. Blood is removed from the great veins and returned to the right atrium and the patient's native circulation is powered entirely by the heart. Veno-pulmonary ECMO (V-PA) drains blood from the right atrium and returns blood to the pulmonary artery (usually via a specialised double-lumen catheter) providing a combination of respiratory and right ventricular support. Veno-arterial ECMO (V-A ECMO) returns blood to the systemic arteries and should not be used to support isolated respiratory failure.

Configuration

The *configuration of V-V ECMO* refers to the way a mode of ECMO is provided. It is defined by the cannulae insertion sites, the type of cannula used and the tip positions (Table 50.1). *Access cannulae* drain blood from the venous system under negative pressure and may be either single-stage or multi-stage. Single-stage cannulae drain blood from a short region near the tip only. Multi-stage cannulae drain blood through side holes over a 15–20 cm length of the cannula, in addition to the tip, and allow a greater negative pressure in the circuit. For this reason, they may provide higher circuit blood flow and are the predominant type of access cannula for V-V ECMO. *Return cannulae* deliver blood back to the patient under positive pressure from the ECMO circuit and expel blood only near the cannula tip (single stage). A double-lumen cannula is available for adult V-V ECMO support (Avalon Elite) that contains both access and return lumens within a single cannula. A longer specialised double-lumen cannulae (Protek Duo) returns blood from the systemic veins to the pulmonary artery and provides a percutaneous configuration for V-PA support. [5], [6]

Table 50.1



Forms of Respiratory ECMO Support: Configurations of V-V ECMO and V-PA ECMO

CONFIGURATION	INSERTION SITE	CANNULA TIP POSITION	CANNULA TYPE AND SIZE	ADVANTAGES / DISADVANTAGES
Femoro-femoral (fem-fem)	*Access:* Right or left femoral vein *Return:* Right or left femoral vein	*Access:* SVC *Return:* Right atrium	*Access:* Multi-stage (21–25F) *Return:* Single-stage (21–23F)	*Advantages:* Rapid to establish, safe, easy to secure and transport *Disadvantages:* Access insufficiency if access cannula not in SVC, re-circulation at high flow
Femoro-jugular (Fem-Jug)	*Access:* Femoral vein *Return:* Right jugular vein	*Access:* SVC *Return:* Right atrium	*Access:* Multi-stage (21–25F) *Return:* Short single-stage (19–21F)	*Advantages:* Full support and infrequent access insufficiency *Disadvantages:* Longer to insert, difficult to secure and maintain dressing, decannulation risk, re-circulation
Dual-lumen/two-stage (Avalon)	Right jugular vein	*Access:* Hepatic IVC and SVC *Return:* Right atrium	31F	*Advantages:* Single cannulation, allows ambulation, minimal re-circulation *Disadvantages:* Difficult to secure and maintain dressings, high circuit pressures, risk of cardiac perforation
Veno-pulmonary artery	Right internal jugular vein	Main *Return* Pulmonary Artery Trunk (Beyond pulmonary valve	31 Fr	*Advantages:* Single insertion site, provides right ventricular support, no re-circulation. Disadvantages: Requires image intensifier (radiology) and prior pulmonary artery cannulation with guidewire exchange (takes longer), risk of cardiac injury, securing challenges.

In all cases, V-V ECMO blood flow travels from the vena cavae to the atria (cavo-atrial flow) to minimise re-circulation.

ECCO $_2$ R

Extracorporeal CO $_2$ removal (ECCO $_2$ R) systems differ from ECMO. They use smaller cannulae, low-blood-flow extracorporeal circuits and oxygenators and predominately remove CO_2.[7] Circuit blood flow is limited to less than 1–2 litres per minute and such systems cannot support patients with minimal lung function or severe hypoxaemia but can eliminate virtually all the CO_2 produced. By controlling CO_2, they facilitate protective lung ventilation.[8] Current $ECCO_2R$ systems may be pump-driven veno-venous systems with a membrane oxygenator (PALP, Maquet or Hemolung RAS)[9] or be ‘pumpless’ and use an arterio-venous mode (iLA Membrane Ventilator Novalung)[10] or utilise a dialysis membrane in addition to the gas exchange membrane (Prismalung, Gambro-Baxter, DECAPsmart, Hemodec).[11]

A large regional, randomised trial to assess the effect of $ECCO_2R$ on survival of screened intubated ICU patients with hypoxic respiratory failure, which was terminated early due to safety and futility, demonstrated similar survival in the $ECCO_2R$ group and the conventional ventilation group and a higher number of serious adverse events including intracerebral haemorrhage with the use of $ECCO_2R$.[12]

Gas Exchange Principles in V-V ECMO

Oxygen Delivery

The quantity of oxygen that can be delivered to the patient on V-V ECMO depends on the quantity of blood arriving at the oxygenator (circuit blood flow), the pre-oxygenator O_2 saturation and the haemoglobin. Current adult membrane oxygenators can oxygenate up to 7 litres of deoxygenated blood flow per minute. Additional FGF to the oxygenator cannot increase the oxygen delivery to the circuit blood. *In the presence of a large pulmonary shunt, the patient’s arterial oxygen saturation will depend predominately on the proportion of deoxygenated venous return that can be captured by the V-V ECMO circuit.* Capturing additional deoxygenated venous blood with ECMO will improve arterial oxygen saturation. The oxygen consumption and haemoglobin will also affect the patient’s arterial oxygen saturation in the presence of a large lung shunt.

Carbon Dioxide Removal

Removal of CO_2 *by the membrane oxygenator is largely determined by the ratio of FGF to circuit blood flow in the oxygenator.* [13] For a given circuit blood flow, increasing the FGF to the oxygenator will increase CO_2 removal. The FGF rate to the membrane oxygenator is titrated to achieve the desired partial pressure of CO_2 in the arterial blood. Normally, the ratio of FGF (L/min) to the circuit blood flow (L/min) at the commencement of ECMO is approximately 1:1. With lung recovery, FGF can be gradually reduced while maintaining circuit blood flow. When the lung is capable of safely removing all CO_2 production, FGF is ceased to the oxygenator and extracorporeal respiration ceases.

Re-circulation

The optimal configuration of V-V ECMO must ensure adequate separation between the access and return cannulae within the venous system to minimise *re-circulation* of ECMO circuit blood flow. [14] Blood entering the oxygenator with high oxygen content can accept little additional oxygen owing to the nature of the oxygen content curve. Capturing recirculated blood will greatly reduce the quantity of oxygen delivery the patient can receive from the ECMO circuit and may be a cause of arterial hypoxaemia on V-V ECMO support. Some degree of re-circulation is inevitable with the V-V ECMO mode, particularly at higher pump blood flow rates. Clinically significant re-circulation results in a reduced colour difference between pre- and post-oxygenator blood (both appear bright red) or an O_2 saturation of over 80% in the pre-oxygenator blood. In contrast to oxygen delivery, re-circulation does not reduce CO_2 clearance. V-PA ECMO for respiratory failure avoids the problem of re-circulation.

High Oxygen Consumption

High cardiac output in conjunction with high oxygen consumption due to sepsis and fever may result in hypoxaemia, despite optimal V-V ECMO configuration, and maximal circuit blood flow of 5–7 L/min. This is associated with low pre-oxygenator oxygen saturation (<60%), fully oxygenated blood returning from the circuit and patient arterial hypoxaemia. It is not uncommon for patients to experience a period of hypoxia even on well-configured V-V ECMO during severe illness (near total lung shunt).

Indications and patient selection for respiratory ECMO support

V-V and V-PA ECMO are indicated for life-threatening forms of acute respiratory failure where the risks of less-invasive support are considered greater than the risks of ECMO. In selected populations where there is a reasonable expectation of long-term survival without severe disability, it provides non-pulmonary respiratory support and allows time for recovery of the underlying condition.

Large, randomised adult ECMO trials for severe respiratory failure conducted by experienced providers to selected populations have demonstrated survival benefits for ARDS and similar findings were observed with COVID-19 cases that received ECMO. [15-17]

Respiratory ECMO support is a complex care pathway that few patients require and survival benefits in low volume and new providers have been observed to be lower than experienced centres which provide a strong rationale for centralisation of care. [18]

Conditions, where the use of V-V ECMO is commonly associated with recovery and favourable outcomes (age <70 and without advanced co-morbidities) despite severe respiratory failure, are:

- ARDS with primary lung injury from infection, [19], [20] aspiration or direct trauma
- primary graft dysfunction following lung transplantation [21]
- pulmonary vasculitis (Goodpasture's, ANCA-associated, autoimmune)
- Bronchopulmonary fistula with severe air leak

Conditions, where recovery is unlikely with the use of ECMO as rescue therapy in the event of severe respiratory failure are:

- respiratory failure associated with long-term immunosuppression (heart, renal, bone marrow transplant recipients, HIV, graft-versus-host disease)
- respiratory failure associated with malignancy [22]
- chronic lung transplant rejection [23]

ECMO may be used as a bridge to lung transplantation in selected patients with advanced forms of irreversible respiratory failure. [24] ECMO should only be used for known cases of irreversible end-stage respiratory failure (cystic fibrosis, interstitial lung disease, chronic obstructive airway disease) *following careful case selection by lung transplant centres* .

The decision to institute ECMO for severe respiratory failure is often complex and clinical triggers and logistic factors must be considered when determining the need for and the timing of ECMO. These include severity of lung injury, adequate trial of less-invasive interventions, rate of lung injury progression, need for inter-hospital transport and risk of bleeding.

Current clinical triggers for V-V ECMO initiation in suitable, intubated patients with ARDS despite recourse to prone ventilation and PEEP of at least 10 cm H_2O [16] include:

- ratio of P_aO_2 to F_iO_2 to < 50 mm Hg (6.7 kPa) for 3 consecutive hours
- ratio of P_aO_2 to F_iO_2 to < 80 mm Hg (10.7 kPa) for 6 consecutive hours
- hypercapnia with pH <7.25 and P_aCO_2 > 60 mm Hg (8 kPa) for 6 consecutive hours with safe mechanical ventilation settings (plateau pressure ≤32 cm H_2O and tidal volume ≤6 mL/kg predicted body weight)

Generally, optimisation of circulatory support (cardiac assessment with echocardiography) using inotropes or volume state therapy (where appropriate) and a trial of high PEEP (18–22 cm H_2O) or pulmonary vasodilator is undertaken prior to ECMO.

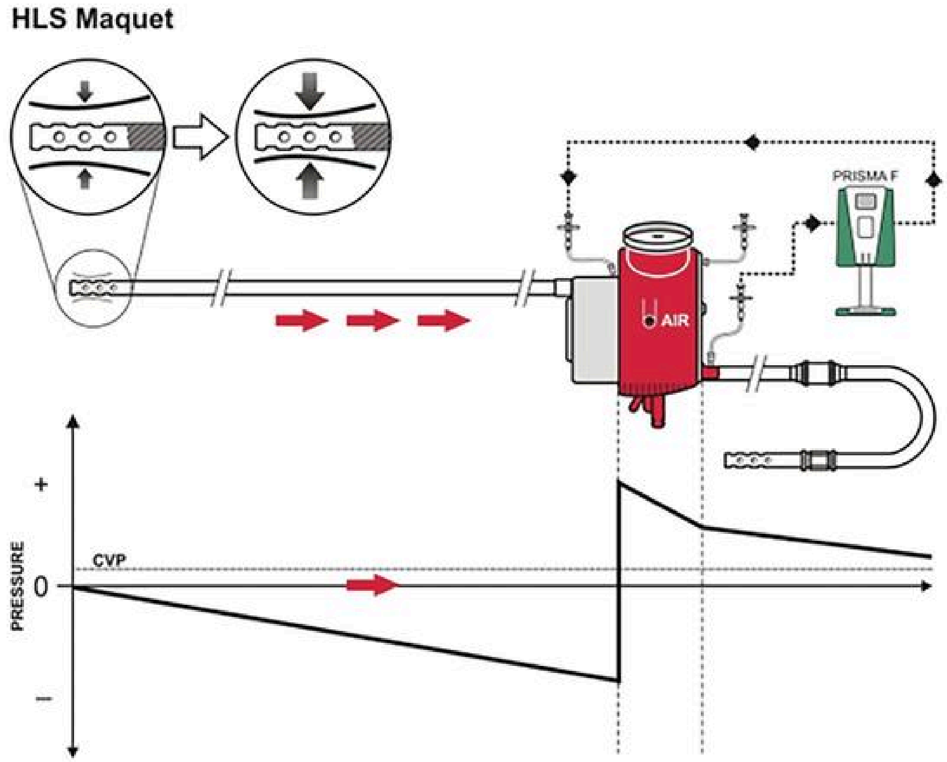
Survival prediction models have been built using worldwide datasets of V-V ECMO patients, such as the RESP, [25] PRESERVE [26] and ECMOnet scores, [27] to aid in risk-adjusting survival from differing institutions and provide a guide to expected outcomes.

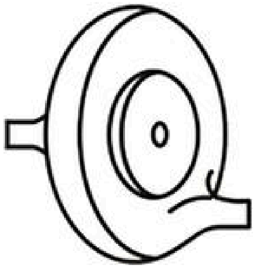
ECMO is a mobile support that can be used across all patient transport modalities (road, fixed wing and helicopter) with very low rates of complications reported. [28-30] Unstable patients with severe respiratory failure requiring inter-hospital transport should be considered for ECMO prior to transfer.

ECMO-Specific Patient Care

Management of Circuit Blood Flow Settings

Rotary (constrained vortex) blood pumps generate circuit blood flow proportional to their pump speed and are afterload sensitive (Fig. 50.1). In V-V ECMO, afterload across the pump is low and stable provided there are no circuit obstructions. Generally, the pump operates in a pump-speed-controlled mode where pump speed is the set variable and resulting pump flow is measured. Pump speed settings are chosen to deliver sufficient circuit blood flow to achieve the required oxygen delivery. Depending on patient size, oxygen consumption and lung shunt, circuit blood flow between 4 and 7 L/min will be required to achieve safe arterial oxygen saturations of over 85% while maintaining safe lung ventilation. Higher circuit flow results in greater re-circulation in V-V ECMO. In V-PA ECMO, afterload is greater, and support is provided with a double-lumen cannula with narrower access and return diameters which reduce achievable circuit flow (3–5 L/min); however, as re-circulation with this mode is negligible, similar patient oxygenation is achievable.





The diagram outlines the high-frequency oscillatory ventilation Maquet system. At the top left, an inset depicts a piston with arrows indicative of oscillatory movement along a tube. The main section depicts the ventilation circuit, where a central unit labelled air connects to a patient by tubes. The circuit includes a monitor and a valve to control airflow, where arrows indicate the direction of air and oxygen flow. Below the circuit, a graph plots central venous pressure against time, where the pressure axis ranges from positive to negative values, and a waveform that oscillates around the zero mark. At the bottom left, a circular component represents the oscillatory mechanism.

FIG. 50.1 **Schematic of current-generation ECMO circuit.** *Arrows* show the direction of circuit blood flow with blood entering the access (drainage) cannula via side and end holes within collapsible veins. Blood is moved by the action of a rotary pump (*see inset*) where blood is 'pulled' into the centre of the pump and 'pushed' out the periphery (side) of the pump. Oxygen and air (fresh gas flow) are provided to the membrane consisting of stacked hollow fibre sheets contained in a sealed chamber where blood and gas remain separate. Gas is contained in the hollow (polymethylpentene) fibres which are surrounded by flowing circuit blood. Circuit connectors provide access for renal replacement in the positive pressure region of the circuit removing the need for separate vascular access. The graph represents the pressure change in the circuit over distance with the maximal negative and positive pressure in the circuit occurring in the pump.

Monitoring of Circuit Pressure

The pressure in the extracorporeal circuit becomes progressively more negative from drainage cannula tip to the pump head (Fig. 50.1). The maximal positive circuit pressure occurs at the outlet of the pump head and falls progressively to the return cannula. The oxygenator is located distal to the pump head and receives blood under positive pressure. The pressure change across the oxygenator gives an indication of clot burden within the oxygenator (oxygenator thrombosis). Current-generation ECMO pumps have integrated pressure monitoring of pre- and post-oxygenator pressure in addition to negative-pressure monitoring at the pump head inlet.

Access Insufficiency

As pump speed is increased, the negative pressure at the access cannulae inlet also becomes more negative. If venous return to the access (draining) ECMO cannula is inadequate for the degree of pump suction, venous 'suck-down' will occur and circuit blood flow will fall and become variable. *Restricted and variable circuit flow with- or without- visible chaotic movement of the access tubing that is worsened by increasing pump speed* *(and improved by decreasing pump speed) is termed access insufficiency.* This situation must be identified and rectified quickly (reducing pump speed) to prevent haemolysis and potential vascular injury. Access insufficiency may prevent adequate circuit blood flow and oxygen delivery. Multi-stage access cannulae distribute the negative circuit pressure over a longer length of a vessel and deliver higher maximal blood flow than similar single-stage access cannulae.

Factors that increase the occurrence of access insufficiency include:

- femoral multi-stage access cannula tip sited too low [31] (at or below right atrium)
- dual-lumen cannula not optimally sited (distal tip sited in the hepatic vein instead of IVC)
- reduced venous return (blood or volume loss, vasodilation, raised intrathoracic or intra-abdominal pressure [coughing, dyssynchronous breathing, constipation, abdominal distension])
- reduced venous capacitance (extrinsic right heart compression)

Titration of Fresh Gas Flow to the Oxygenator

Fresh gas flow (FGF) to the oxygenator maintains the diffusion gradients for O_2 delivery to, and CO_2 removal from, the circuit blood. FGF can be composed of dry air–oxygen mix or pure O_2. The partial pressure of O_2 in the FGF determines the post-oxygenator blood partial pressure of O_2. The FGF rate determines the partial pressure of CO_2 in the post-oxygenator and its rate is chosen to achieve the desired partial pressure of CO_2 in the patient's arterial blood while maintaining safe lung ventilation.

Lung ventilation

Non-injurious lung ventilation is a primary goal of ECMO support in respiratory failure. Non-pulmonary gas exchange facilitates low pressure and volume strategies and several lung ventilation modes have been advocated during the different phases of ECMO support. PEEP levels are chosen to maintain lung aeration. Peak lung pressures can easily be maintained below 30 cm H_2O with ECMO support. A low driving pressure (plateau pressure –PEEP) may be beneficial, [32] as such, tidal volumes may be negligible and remain much less than the anatomical dead space of the lung during ECMO support. Improving lung compliance and the return of physiological tidal volume herald lung recovery from acute lung injury. Prone positioning is not contraindicated during respiratory ECMO and its benefits are currently being trialled. Extubation is also possible during respiratory ECMO support.

Weaning

As lung recovery occurs it is standard to wean ECMO FGF until it is off, at which point the patient is no longer receiving extracorporeal support. Cannulae are generally removed after a period of gas flow (usually 2–24 hours). There is no need to wean circuit blood flow below 3 L/min during weaning, which reduces the need for additional anticoagulation. Percutaneously inserted venous cannulae can be removed at the bedside (off anticoagulation) and skin sites compressed for 20 minutes or sutured.

In general, ECMO weaning and decannulation are performed in advance of airway extubation. Where ECMO is used in chronic respiratory failure conditions, it can be advantageous to extubate patients during ECMO support to maintain wakefulness and avoid the complications of sedation. Ambulant ECMO is highly desirable for cystic fibrosis patients being bridged to transplantation to maintain secretion clearance. [33] Whether extubation, early tracheostomy or active physical therapy during respiratory ECMO provides additional benefit for patients with acute respiratory failure is currently uncertain.

Anticoagulation

Anticoagulation for ECMO is given to reduce the rate of clot formation within the circuit and reduce clot formation associated with cannulae. [34] Clotting is often seen in low-flow regions of the oxygenator but is not an indication of circuit change. It is generally accepted that systemic anticoagulation with heparin should be provided for all patients on ECMO *provided there is no bleeding and there is no anticipated or recent surgery* . Anticoagulation practices are based on patient bleeding risk profiles and V-

V ECMO can be successfully run for days without anticoagulation to arrest bleeding. Essential surgery can also be performed during ECMO support. [35]

ECMO-Specific Patient Complications

Prevention of complications is fundamental to successful ECMO care. Patients are at increased risk of bleeding, particularly from the injured lung, and have an increased risk of haemolysis. V-V ECMO can provide great stability to the patient with severe respiratory failure but may also induce dangerous complications if the circuit is breached (accidental decannulation, circuit rupture) or the blood pump fails. Staff training and resources to standardise decision-making are important components of successful ECMO programmes. Avoiding excessive sedation and incremental positive fluid balance, provision of timely pressure care and physical therapy during V-V ECMO support are now standard.

Bleeding

Bleeding remains the main complication of ECMO; however, many sources of bleeding can be prevented. Cannulation site bleeding should be uncommon in V-V ECMO if optimal percutaneous cannulation techniques are used and surgical dissection is avoided. Pulmonary bleeding is a frequent cause of death during V-V ECMO support for respiratory failure. [36] Insertion of intercostal catheters during ECMO is an extremely high-risk intervention and should not be performed unless no other alternative remains. In particular, intercostal catheters should not be inserted for pneumothoraces or pleural fluid drainage unless they are massive or cause haemodynamic compromise. [37] During V-V ECMO, pneumothoraces may be managed by increasing ECMO support and reducing (or ceasing) pulmonary ventilation without the need for tube insertion. Fibrinolysis and secondary consumptive coagulopathy can occur during ECMO, particularly with older circuits and induce generalised bleeding. Monitoring of fibrinogen and d-dimer levels and elective ECMO circuit changes are required to control this process.

Haemolysis

Haemolysis (repeated plasma-free Hb >0.1g/dL) is uncommon with current-generation circuits; however regular monitoring of plasma-free Hb is still routine in many centres. Severe haemolysis (plasma-free Hb >1.0 g/L or with hyperkalaemia or red urine) suggests pump head thrombosis and must be treated with an urgent circuit change. [38]

Air embolism

Air will rapidly enter the circuit during pump operation if there is any breach in the negative-pressure region of the circuit. Taps and other potential breaches on the negative (pre-pump) side of the circuit should be avoided. Venous central line lumen near the ECMO access cannula may also entrain air if not closed to the atmosphere. Air that enters the circuit will de-prime the pump head (reducing circuit flow), accumulate in the oxygenator and may reach the return line and cause patient air embolism. Staff education and circuit design are essential preventative measures. De-airing the circuit following air embolism is technically challenging.

Enteral and parenteral nutrition

Yasmine Ali Abdelhamid, Marianne Chapman and Adam M. Deane

It is standard practice to provide nutritional support to critically ill patients with the aim of providing essential nutrients to prevent malnutrition and minimise muscle wasting; the latter being inevitable with any period of bedrest, critical illness itself or its treatment. [1] Critical illness is characterised by nutrient-resistant catabolism, insulin resistance and anabolic resistance to dietary protein. Whilst it is intuitively appealing that optimal nutritional support and/or nutritional supplements may reduce mortality and improve recovery, data from several large clinical trials do not support this concept. [2-7] Understanding in this area is rapidly changing and hence, international clinical practice guidelines may not always represent current best practice. [8-10]

Nutritional Assessment

Objective assessment of nutritional status is difficult in the critically ill because disease processes confound methods used in the general population. Anthropometric measures, such as triceps skin-fold thickness and mid-arm circumference, are obscured by oedema. Ultrasound measurement of skeletal muscle thickness is affected by oedema and interobserver variability. [11] Quantification of muscle strength, such as voluntary handgrip strength, is impractical in unconscious or sedated patients. Laboratory measurements, including transferrin, pre-albumin and albumin concentrations, lymphocyte counts and skin-prick test reactivity, are affected by critical illness and unrelated to nutritional status. Including subjective clinical evaluation (dietary history and clinical examination) may be more informative than relying on a single objective measurement.[12] Historical features of malnutrition include a history of weight loss, poor diet, gastrointestinal symptoms, reduced functional capacity and a diagnosis associated with poor intake. Physical signs include loss of subcutaneous fat, muscle wasting, peripheral oedema and ascites.

Imprecision with nutritional assessment in the critically ill has led to attempts to define a group of patients at greater nutritional risk, in whom optimal support may be of greatest benefit. A number of scoring systems[13-16] (Table 51.1) have been developed but none have been shown to accurately identify a group of patients who have nutritional requirements differing from the general ICU population. Furthermore, in the identification of those who are malnourished, it remains uncertain how their nutritional support should be managed. There is some concern that aggressive administration of nutrition to malnourished patients can be associated with increased harm.[17, 18]

Table 51.1

Screening and assessment tools for evaluation of nutrition status

TOOL	FEATURES	STRENGTHS AND WEAKNESSES
Subjective Global Assessment (SGA) [13]	Includes patient history (weight loss, dietary intake change, gastrointestinal and functional impairment) and physical examination (loss of subcutaneous fat, muscle wasting, ankle oedema, sacral oedema and ascites)	Frequently used Relies on subjective assessment Only classifies subjects into three general groups (well nourished, moderately malnourished and severely malnourished) and does not reflect subtle changes in nutritional status Not designed specifically for the ICU setting
Nutritional Risk Screening (NRS) [14]	Based on weight loss, BMI, decreased food intake and severity of the disease	Determines both nutrition status and disease severity Generic tool for use in the hospital setting Validated in the ICU setting
Nutrition Risk in Critically Ill (NUTRIC)	Comprised age, APACHE II and SOFA scores, number of	Determines both nutrition status and disease severity

TOOL	FEATURES	STRENGTHS AND WEAKNESSES
Score - modified [15]	comorbidities and number of days in hospital before ICU admission	Validated in the general ICU population as identifying a group with worse outcomes
Global Leadership on Malnutrition (GLIM) Criteria [16]	Presence of at least 2 of 3 clinical items (non-volitional weight loss, low BMI, reduced muscle mass) and at least 1 of 2 aetiologic items (reduced nutrient intake or increased disease burden)	Awaiting validation in the ICU setting

---

APACHE , Acute physiology and chronic health evaluation; *BMI* , body mass index; *SOFA* , sequential organ failure assessment.

Patient Selection and Timing

Most clinicians consider nutritional support in patients who the clinician anticipates will remain in the ICU for more than 1–2 days but are unable to ingest food orally. Meta-analyses of a number of small clinical trials suggest that commencing at least some enteral nutrition (EN) within 48 hours of ICU admission increases survival and reduces infective complications compared with delayed enteral intake. [19] , [20] Rather than this being due to an improved nutritional state, it may be a direct effect of the presence of nutrients in the intestinal lumen stimulating gastrointestinal blood flow, reducing permeability and stress ulceration and bleeding. [21-23]

Commencing EN whilst a patient is haemodynamically unstable or receiving vasopressors is contentious. Nutrient within the gastrointestinal lumen stimulates blood flow to the mesenteric arteries.[22] The physiological concern is that the increase in splanchnic blood flow may be limited in shock states, introducing the risk of splanchnic underperfusion, intestinal ischaemia and feed intolerance.[24] In addition, blood flow may be diverted away from other vital organs to the gastrointestinal tract. A large multicentre, open-label clinical trial reported that restricting calorie and protein provision in ventilated patients who were receiving a vasoactive drug for 7 days to 6 kcal/kg per day and 0.2–0.4 g/kg per day protein reduced the time to 'readiness for ICU discharge' by one day when compared to those receiving 25 kcal/kg per day and 1.0–1.3 g/kg per day protein.[25] The authors did not detect any harm with this approach. Based on existing data a reasonable treatment strategy for ventilated patients with shock is to commence EN with no need to prioritise getting to full feeding within the first 7 days if enteral feed intolerance is encountered.

In patients who are previously well nourished but are unable to receive EN acutely, or for those patients who are not meeting energy targets with EN alone, international clinical practice guidelines recommend not initiating parenteral nutrition (either supplemental or total) prior to day 7 of ICU admission.[9, 18, 26]

Nutritional Requirements of the Critically Ill

Energy

Energy expenditure can be estimated using weight-based equations or measured using indirect calorimetry. Equations can be simple (20–25 kcal/kg/day),[27] or more complex (Harris-Benedict, Schofield).[28, 29] The latter were derived with the aim of more accurately predicting measured energy expenditure; however, none reliably predict measured energy expenditure in all patients.[30] Measurement of energy expenditure is time-consuming and cumbersome with potential inaccuracies, and its routine use is restricted to specialised centres.[31] Intuitively, the concept of providing energy to meet energy expenditure has merit; however, studies to date have failed to confirm that this practice improves patient-centred outcomes.[32-34] Hence 20–25 kcal/kg/day is a frequently adopted target. Furthermore, it remains uncertain what weight should be used for these calculations. Actual body weight early in critical illness may be inflated by fluid resuscitation. Feeding to actual body weight may be excessive in patients who are obese whilst feeding to ideal body weight may be insufficient.

Several large randomised clinical trials have evaluated calorie delivery of between 12 and 25 kcal/kg/day during early critical illness.[2-5,35] These data indicate that increased enteral calorie delivery is associated with more upper gastrointestinal intolerance and hyperglycaemia, but does not influence either mortality or functional recovery. The safety of prolonged fasting, or providing <12 kcal/kg/day, and delivery of more than 25 kcal/kg/day, have not been studied. However, so-called ‘overfeeding’ may not be a safety issue when nutrition is delivered solely by the enteral route.[36] It is possible that optimal intake varies between patients, depending on yet unidentified patient factors, and within a patient, depending on the phase of critical illness.

It is generally accepted that patients receive only about 60% of nutrition prescribed enterally due mainly to gastrointestinal intolerance and fasting for procedures. Hence a prescription of 25 kcal/kg/day with an expectation that only about 60% will be delivered would appear adequate early in the ICU stay.

The current clinical practice guidelines recommend that indirect calorimetry be used to determine energy requirements when available, otherwise published predictive equations or simple weight-based equations can be used.[8,10] Guidelines recommend feeding between 12 and 25 kcal/kg/day for the first 7–10 days of ICU stay.[9] The clinical practice guidelines from the European Society for Parenteral and Enteral Nutrition (ESPEN) recommend fewer calories during the first days of ICU stay (acute phase) with an increase over time.[10] This recommendation was made despite the lack of supportive data.

Protein

The dietary protein requirement for healthy humans is around 0.8 g/kg/day. Clinical practice guidelines recommend a range of 1.2–2.5 g/kg/day of protein in critical illness, with higher doses suggested for at-risk patient groups such as those with burns or multitrauma.[8, 10] However, these recommendations are based on scant evidence, and there is no evidence from meta-analyses that greater protein administration improves outcomes.[37-39] The largest clinical trial conducted in this field was open-label and examined the provision of 'high-dose protein' (≥2.2 g/kg/day) with 'usual dose protein' (≤1.2 g/kg/day) in mechanically ventilated adults with at least one nutritional risk factor. Greater protein did not reduce mortality or time to hospital discharge.[40] Further data from current trials will soon become available (ClinicalTrials.gov NCT04633421 & Australian New Zealand Clinical Trials Registry number 12621001484831). Importantly it appears that although enteral protein is absorbed, integration of protein into muscle is attenuated in the critically ill.[41] The safety of more protein in certain groups of patients, for example those with acute renal impairment, remains uncertain.[40, 42]

Micronutrients

Critical illness may increase the requirements for vitamins B1 (thiamine), B12, C, D, iron, selenium and zinc.[43] Thiamine, folic acid and vitamin K are particularly vulnerable to deficiency during total parenteral nutrition (TPN). Renal replacement therapy can cause loss of water-soluble vitamins and trace elements. Deficiencies of selenium, zinc, manganese and copper have been described in critical illness, in addition to the more familiar iron-deficient state. It has been suggested that subclinical deficiencies in critically ill patients cause immune deficiency and reduced resistance to oxidative stress. Suggested requirements for micronutrients in critically ill patients vary between authors and depending on route of administration; the most comprehensive guidance[43] is reproduced in Tables 51.2 and 51.3 .

Table 51.2

Daily vitamin requirements in critical illness

VITAMIN	FUNCTION	AMOUNT
Vitamin A	Cell growth, night vision	3300–4500 IU
Vitamin D	Calcium metabolism	600–1000 IU
Vitamin E	Membrane antioxidant	15–40 mg
Vitamin K	Activation of clotting factors	120–150 µg
Thiamine (vitamin B1)	Oxidative decarboxylation	10–300 mg
Riboflavin (vitamin B2)	Oxidative phosphorylation	3.6–10 mg
Niacin (vitamin B3)	Part of NAD, redox reactions	18–40 mg
Pantothenic acid (vitamin B5)	Part of coenzyme A	5–15 mg
Pyridoxine (vitamin B6)	Decarboxylase activity	4–7.5 mg
Biotin (vitamin B7)	Carboxylase activity	30–75 µg
Folic acid (vitamin B9)	Haematopoiesis	500–1000 µg
Vitamin B12	Haematopoiesis	5–7.5 µg
Vitamin C	Antioxidant, collagen synthesis	200–500 mg

From Berger MM, Shenkin A, Schweinlin A, et al. ESPEN micronutrient guideline. *Clin Nutr.* 2022;41(6):1357-1424.

Table 51.3

Daily trace element requirements in critical illness

ELEMENT	FUNCTION	AMOUNT
Selenium	Antioxidant, fat metabolism	100–200 µg
Zinc	Energy metabolism, protein synthesis, epithelial growth	5–20 mg
Copper	Collagen cross-linking, ceruloplasmin	0.5–3 mg
Manganese	Neural function, fatty acid synthesis	3–55 mg
Chromium	Insulin activity	15–200 µg
Cobalt	B12 synthesis	Not required as long as vitamin B12 is administered
Iodine	Thyroid hormones	130–300 µg
Iron	Haematopoiesis, oxidative phosphorylation	1–30 mg
Molybdenum	Purine and pyridine metabolism	19–250 µg

From Berger MM, Shenkin A, Schweinlin A, et al. ESPEN micronutrient guideline. *Clin Nutr.* 2022;41(6):1357-1424.

Commercial preparations of both enteral and parenteral feeding solutions provide standard amounts of micronutrients. Supplementation of intake of certain antioxidant vitamins and trace elements above these levels is discussed below. The actual requirements for most vitamins and trace elements during critical illness are unknown. It also remains uncertain whether treating a measured deficiency will improve patient outcomes.

Route of Nutrition

When possible, patients should be fed enterally rather than intravenously as EN is cheaper and simpler. Clinical trials report no benefit with the parenteral route.[18, 44] In the CALORIES trial, 2388 patients who could be fed by either route were randomly assigned to receive nutritional support parenterally or enterally for up to 5 days with no statistical difference in the primary outcome of mortality or other secondary outcomes.[44] The EPaNIC trial compared early parenteral supplementation of inadequate enteral intake (within 48 hours of ICU admission) with supplementation delayed until day 8.[18] There was no mortality difference, but patients in the delayed-supplementation group left the ICU earlier and suffered fewer infectious complications.

These data suggest that whilst parenteral nutrition can be administered as a safe alternative to EN, there is no compelling evidence to commence parenteral nutrition early in ICU admission.

Enteral Nutrition

Access

Nasal tubes are preferred to oral, except in patients with a basal skull fracture, in whom there is a risk of cranial penetration. Smaller gauge tubes may be more comfortable than larger gauge tubes, but the latter allow the measurement of gastric residual volumes which can be used as a surrogate measure to determine the success or tolerability of EN (see later). The position of all tubes must be checked before feeding is started, as misplacement is not uncommon and intrapulmonary delivery of feed is potentially fatal.

Nasojejunal tubes can be considered if gastric emptying is delayed and refractory to prokinetic agents (see later).[45]

Regimen

Nasogastric feeding can be started at the goal rate or started slowly and incremented to the goal rate. Large gastric residual volumes are seen more often in patients in whom feeding is initiated at goal rate [2,4] but the clinical significance of this is questioned. Some clinical practice guidelines recommend commencing at a slower rate, for example 20 to 40 mL/h and increasing the rate over 24–48 hours depending on tolerance. [10]

Traditionally, gastric residual volumes are assessed by aspiration of the tube every 4–6 hours. This dogma has been challenged based on data suggesting that monitoring gastric residual volumes does not decrease the prevalence of ventilator-associated pneumonia. [46] Nevertheless, values greater than 250 mL provide a bedside indication of delayed gastric emptying [47] which is associated with worse clinical outcomes. [48] Patients with delayed gastric emptying can be treated with prokinetic agents (erythromycin 200 to 250 mg q12h and metoclopramide 10 mg q8h to q6h intravenously), which will accelerate gastric emptying and reduce the prevalence of enteral feed intolerance, [49] although effects on other patients outcomes are as yet uncertain. [50]

Composition

Commercially available enteral feeding formulae vary widely in composition. Polymeric formulae are most commonly used and contain intact proteins (derived from whey, meat, soy isolates and caseinates) and carbohydrates in the form of oligo- and polysaccharides. These require pancreatic enzymes for absorption.

For most patients, elemental feed formulae with defined nitrogen sources (amino acids or peptides) provide no meaningful benefit and are more expensive. They may enable feeding when small bowel absorption is impaired, for instance in pancreatic insufficiency or following prolonged starvation. Lipids are usually provided by vegetable oils consisting mostly of long-chain triglycerides, but some also contain more easily absorbed medium-chain triglycerides. The proportion of non-protein calories provided as carbohydrates is usually two-thirds.

Electrolyte composition varies widely between formulae, with sodium- and potassium-restricted formulations available. Vitamins and trace elements are usually added by the manufacturers so that daily requirements are present in a volume containing roughly 2000 kcal. The possible benefits of providing additional doses of some of these substances to critically ill patients are considered below. There is no known benefit to adding probiotics or fibre to enteral feed formulae.[8, 51]

Complications

Enteral feeding is an independent risk factor for ventilator-associated pneumonia.[52] Fine-bore tubes are vulnerable to misplacement in the trachea or to perforation of the pharynx, oesophagus, stomach or bowel. Metabolic complications include electrolyte abnormalities and hyperglycaemia. Severely malnourished patients are at risk of refeeding syndrome (see below).

Parenteral Nutrition

Parenteral nutritional support is indicated when the enteral route is not possible and when adequate enteral intake cannot be established within an ‘acceptable’ time. In previously well-nourished patients this is 5 to 7 days.

Parenteral feeding solutions may be prepared from their component parts under sterile conditions. Ready-made solutions exist and may be more practical. In ICU patients, the daily requirements are infused continuously over 24 hours. Careful biochemical and clinical monitoring is important, particularly at the outset (Box 51.1).

Box 51.1

Minimum monitoring during total parenteral nutrition – less stable patients may require more intensive surveillance

Nursing

1. Temperature
2. Pulse
3. Blood pressure
4. Respiratory rate
5. Fluid balance
6. Blood glucose (4-hourly when commencing parenteral nutrition)

Daily (at least)

1. Review of fluid balance
2. Review of nutrient intake
3. Blood glucose
4. Urea, electrolytes and creatinine
5. Magnesium, calcium and phosphate

Weekly (at least)

1. Full blood picture
2. Coagulation screen
3. Liver function tests
4. Lipids
5. Weight

As indicated

1. Zinc
2. Uric acid

Access

The major concern with central venous access for parenteral nutrition is prevention of infection. If a multi-lumen catheter is used, one lumen should be dedicated to the administration of nutrition therapy. Three-way taps should be avoided and infusion set changes carried out daily under sterile conditions. For long-term parenteral nutrition, specialised catheters with a tunnelled cuff or a subcutaneous port are recommended, or peripheral inserted central catheters may be required.

Composition

Energy

Energy is usually provided by a combination of carbohydrates and lipids. The optimal balance between the two is unknown; often 30%–40% of non-protein energy is given as lipid. Glucose is the preferred carbohydrate and is infused as a concentrated solution. Exceeding the body's capacity to metabolise glucose (4 mg/kg/min in the septic patient) can lead to hyperglycaemia, lipogenesis and excess CO_2 production. Endogenous insulin secretion is stimulated in response to increasing blood glucose. However, many patients require additional insulin, particularly patients with diabetes.

Lipid provides essential fatty acids (linoleic and linolenic acids) and is a more concentrated energy source than glucose. It may thus avoid the complications of excess glucose administration. Traditionally, lipid preparations consist of soybean oil emulsified with glycerol and egg phosphatides. It has been proposed that replacing some or all of the soybean oil with olive oil- or fish-oil-based lipids or with medium-chain triglycerides may offer immunological benefits but there is no high-quality evidence that this approach is of benefit to patients.[53] Alternatively, glucose may be relied upon for almost all the energy, with lipid being infused once or twice a week to provide essential fatty acids.

Nitrogen

Nitrogen is supplied as crystalline solutions of L-amino acids. Commercially available preparations vary in their provision of conditionally essential amino acids. Glutamine, tyrosine and cysteine are absent from many because of instability.

Micronutrients

Vitamin and trace element preparations are added frequently to parenteral solutions in appropriate amounts. Thiamine, folic acid and vitamin K are particularly vulnerable to depletion and additional doses may be necessary.[43]

Electrolytes

Amino acid preparations contain varying quantities of electrolytes; additional amounts may be added as needed.

Complications

- *Catheter-related sepsis* is addressed above. Other complications of central venous cannulation are discussed in Chapter 24 .
- *Electrolyte abnormalities* include hypophosphataemia, hypokalaemia and hypomagnesaemia, especially in the first 24–48 hours.
- *Hyperchloraemic metabolic acidosis* may result from amino acid solutions with a high chloride content. Replacing some chloride with acetate in the parenteral solution will resolve this where necessary.
- *Rebound hypoglycaemia* may occur when parenteral nutrition is discontinued suddenly. Total parenteral nutrition should be weaned over a minimum of 12 hours. If it cannot be continued, an infusion of 10% dextrose should be started and blood glucose monitored.
- *Refeeding syndrome* may occur when normal intake is resumed after a period of starvation. It is associated with profound hypophosphataemia, and possibly hypokalaemia and hypomagnesaemia. With the restoration of glucose as a substrate, insulin secretion is stimulated leading to cellular uptake of these ions. Depletion of adenosine triphosphate (ATP) and 2,3-diphosphoglyceric acid (2,3-DPG) results in tissue hypoxia and failure of cellular energy metabolism. This may manifest as cardiac and respiratory failure, with paraesthesia and seizures also reported. Thiamine deficiency may also play a part. Mild hypophosphatemia is very common and is not associated with negative sequelae.

- *Elevated liver enzymes* are common during parenteral nutrition. Causes include hepatic steatosis, intrahepatic cholestasis and biliary sludging from gallbladder inactivity.
- *Deficiencies* of trace elements and vitamins (especially thiamine, folic acid and vitamin K) may occur.

Nutrition and Specific Diseases

Acute Renal Failure

The availability of continuous renal replacement therapy means that dietary fluid and protein restriction are rarely required in the ICU. The use of specialised lipid or amino acid formulations in parenteral nutrition is not supported by evidence, and in general normal nutritional support is appropriate.

Liver Disease

Energy requirements in ICU patients are not altered by the presence of chronic liver disease. Protein restriction has previously been advocated in patients with chronic hepatic encephalopathy; however, modern practice is to provide a normal protein intake. Neither the routine use of feeds enriched with branched-chain amino acids (BCAAs) nor intravenous supplementation with BCAAs is indicated. [8] Thiamine and fat-soluble vitamin deficiencies are common in patients with chronic liver disease.

Acute liver failure reduces gluconeogenesis; hypoglycaemia is a common problem necessitating glucose infusion. Energy and protein requirements are unaltered. In patients with cerebral oedema and markedly increased plasma ammonia concentrations, brief protein restriction may help.

Respiratory Failure

Oxidation of fat produces less carbon dioxide than glucose. There have been attempts to use this premise to assist in weaning from mechanical ventilation by providing 50% of energy intake as lipids rather than carbohydrates. Recent large clinical trials do not support this approach. [2] The supplementation of omega-3 fatty acids in patients with acute respiratory distress syndrome (ARDS) is discussed later.

Acute Pancreatitis

Historically, TPN was a cornerstone of the management of severe acute pancreatitis with the belief that this would minimise pancreatic stimulation. It is now clear that both gastric and jejunal feeding are safe and effective and associated with reductions in infective complications and improved survival compared with TPN. [54] Elemental feeds and pancreatic enzyme supplements may be required if malabsorption is a problem.

Obesity

It has been hypothesised that obese patients should receive hypocaloric, high-protein feeding, [55] however there is insufficient evidence to justify feeding obese patients differently from others. [2, 4] Patients who have undergone some forms of bariatric surgery (especially sleeve gastrectomy and gastric bypass) are at increased risk for micronutrient deficiency, including iron, selenium, copper, zinc, thiamine, folate and vitamins B12 and D.

Adjunctive Nutrition

Certain nutritional substances have been studied as supplements to nutritional support, in attempts to modulate the metabolic and immune responses to critical illness. In general, no benefit has yet been shown in unselected critically ill patients.

Glutamine

Both enteral and parenteral glutamine supplements have been extensively investigated. In large trials, glutamine supplementation either has no effect or is harmful. [6, 56, 57] Its use is not justified.

Selenium

Low plasma selenium concentrations occur frequently in ICU patients. Whilst a number of small studies indicated potential benefits, larger randomised clinical trials reported no benefit. [58], [59] Selenium supplementation is not justified.

Antioxidant Vitamins

Vitamins A, C and E are involved in systemic defence against oxidant stress and have been studied in various doses and combinations. Vitamin C has received particular interest in recent times but, despite initial promise, large randomised controlled trials have not shown a benefit. [60], [61] Interest and trials continue but outside of randomised controlled trials, supplementation with antioxidant vitamins cannot be justified.

Arginine and Immunonutrition

Several commercially available enteral feeding solutions combine omega-3 fatty acids, arginine, nucleotides and in one case glutamine to produce so-called immune-enhancing diets. There is no evidence to support their use with meta-analyses suggesting an increase in mortality when arginine supplementation was given to septic patients. [62], [63] An interim safety assessment of a trial led to its early cessation when this finding was replicated in the subgroup of patients with sepsis. [64]

The addition of omega-3 fatty acids, often in combination with antioxidant vitamins and borage oil has also been studied and again interpretation of the data overall does not support supplementation with omega-3 fatty acids, alone or in combination with other compounds. [65], [66]

Conclusion

In summary, enteral feeding should be commenced early via a nasogastric tube, although there is no need to provide full calorie delivery over the first few days. Intravenous feeding can be commenced on about day 7 if the enteral route is not available or insufficient. The optimal dose of protein is not yet known.

Acute gastrointestinal bleeding

Sheng Qiu, Constantinos Simillis and Shahnawaz Rasheed

Introduction

Acute gastrointestinal bleeding (or haemorrhage) is a common major medical emergency and a common reason for admission to the intensive care unit (ICU).[1] It may result in significant morbidity and mortality, with mortality rates ranging from 4% to 10%.[1–4] The majority of cases die of causes not directly related to bleeding, but due to significant co-morbidities such as cardiopulmonary or multiorgan failure.[2, 5, 6] This observation emphasises the benefit of good supportive care in the ICU for patients presenting with gastrointestinal bleeding.

Upper gastrointestinal bleeding is that originating proximal to the ligament of Treitz, and this includes the oesophagus, stomach and duodenum. Lower gastrointestinal bleeding is that originating from the small bowel and colon. Peptic ulcer disease accounts for 75% of upper gastrointestinal bleeding. Bleeding from varices, oesophagitis, duodenitis and Mallory–Weiss syndrome each account for between 5% and 15% of cases.[2–4] About 20% of gastrointestinal bleeding arises from the lower gastrointestinal tract, commonly due to diverticular disease.[2–4] Common aetiological causes for gastrointestinal bleeding are listed in Box 52.1 .

Box 52.1

Common causes of acute gastrointestinal bleeding

Upper gastrointestinal bleeding

- Peptic ulcers (duodenal ulcer:gastric ulcer, 3:1)
- Varices (oesophageal varices:gastric varices, 9:1)
- Portal hypertensive gastropathy
- Mallory–Weiss syndrome
- Gastritis, duodenitis and oesophagitis

Lower gastrointestinal bleeding

- Diverticular bleeding
- Angiodysplasia and arteriovenous malformation
- Colonic polyps or tumours
- Meckel diverticulum
- Inflammatory bowel diseases
- Haemorrhoids, anal fissure

Resuscitation

Patients with acute gastrointestinal bleeding should have immediate and continual assessment with appropriate management of airway, breathing and circulation. Airway compromise should be managed with immediate basic airway manoeuvres or, if needed, advanced airway manoeuvres. The goals of managing a patient with acute gastrointestinal bleeding are, first, to resuscitate, second, to control active bleeding and, third, to prevent recurrence of haemorrhage. Either colloid or crystalloid solutions may be given through large-bore intravenous cannulae to achieve volume restoration prior to administering blood products. A restrictive transfusion threshold (e.g. haemoglobin concentration of 70–80 g/L) is recommended by major guidelines in the context of non-life-threatening gastrointestinal bleeding.[7,8] In life-threatening bleedings, the local major haemorrhage protocol may be activated, and the patient is transfused with blood, platelets, and clotting factors. Anticoagulation medication, such as aspirin, clopidogrel, warfarin, new oral anticoagulants, non-steroidal anti-inflammatory drugs (NSAIDs), should be stopped in the acute setting. Clinicians must balance the risk of bleeding against the risk of thrombotic events. A multidisciplinary approach involving haematology, cardiology/neurology and gastroenterology is necessary when managing patients on anticoagulant medications, particularly in the reversal of new direct oral anticoagulants. For patients taking warfarin, vitamin K should be given in addition to prothrombin complex concentrate. Similarly, it is important to correct coagulopathies associated with critical illness in the treatment of GI bleeding. Vital signs should be closely monitored. Significant gastrointestinal bleeding is indicated by syncope, haematemesis, systolic blood pressure below 100 mm Hg, postural hypotension and a blood transfusion requirement of more than four units of blood in 12 hours to maintain blood pressure. In patients with hypovolaemic shock, invasive haemodynamic monitoring and hourly urine output should be observed.

Upper Gastrointestinal Bleeding

Clinical Presentation

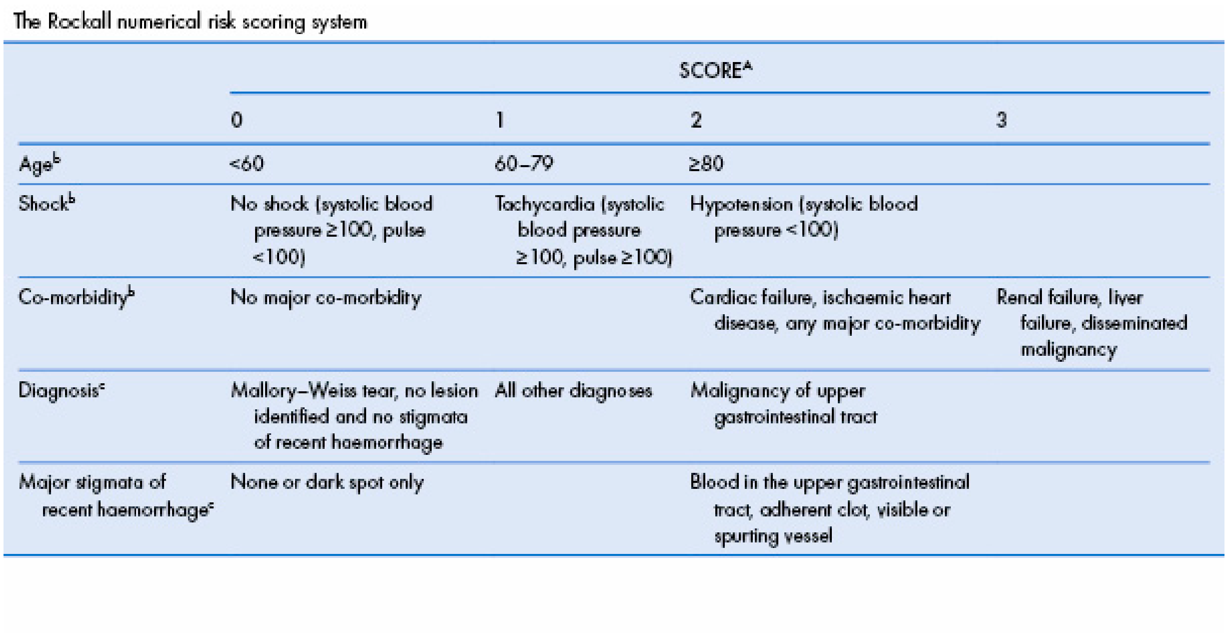
Haematemesis and melaena are the most common presentations of acute upper gastrointestinal bleeding. Bright red haematemesis usually implies active haemorrhage from the oesophagus, stomach or duodenum. There may be epigastric pain, but bleeding ulcers can be painless, especially in elderly patients and users of NSAIDs. A history of vomiting and retching preceding haematemesis suggests Mallory–Weiss syndrome. Coffee-ground vomitus refers to the vomiting of black material which is assumed to be blood. Melaena is the passage of black tarry stools usually due to acute upper gastrointestinal bleeding. Haematochezia is the passage of bright red or maroon blood from the rectum, in the form of pure blood or blood mixed with stool, and usually represents a lower intestinal source of bleeding, although it may be a feature of massive upper gastrointestinal bleeding. In cases of massive gastrointestinal bleeding leading to hypovolaemic shock, the patient may exhibit symptoms and signs of tachycardia, tachypnoea, hypotension, anxiety or confusion, pallor, sweating and oliguria.

Risk Assessment

Risk factors associated with poor outcomes in patients presenting with acute upper gastrointestinal bleeding include being an inpatient, older age (>60 years), significant co-morbidity (especially cardiac failure or malignancy), liver disease/cirrhosis, known varices, haemodynamic disturbance (hypotension with systolic blood pressure <100 mm Hg, tachycardia with pulse ≥100 beats/min), and witnessed haematemesis or haematochezia (suspected continued bleeding after admission).[2,4,9-11]

To assess the risk of serious adverse events or the need for intervention, formal risk assessment scoring systems may be used such as the Rockall scoring system and the Blatchford scoring system.[7,12] The Rockall scoring system, which is used to predict rebleeding and mortality risk, is based on a combination of clinical and endoscopic findings.[7] The initial (pre-endoscopic) Rockall score is derived from age (0–2 points), shock (0–2 points) and co-morbidity (0–3 points). If the pre-endoscopic score is above 0, there is a significant risk of mortality (score 1: predicted mortality 2.4%; score 2: predicted mortality 5.6%) requiring hospital admission and endoscopy, whereas those patients scoring 0 can be safely discharged with outpatient follow-up.[5] The final post-endoscopy score has additional points for endoscopic diagnosis (0–2 points) and endoscopic stigmata of recent haemorrhage (0–2 points), giving a maximum score of 11 points (see Table 52.1). Patients with a post-endoscopic Rockall score of less than 3 have a low risk of rebleeding or mortality and should be considered for early discharge and outpatient follow-up. Increasing post-endoscopic Rockall score leads to a higher risk of rebleeding and death, and should be used in association with other clinical factors in assigning patients to different levels of care.

Table 52.1



The Rockall numerical risk scoring system

	SCORE[a]			
	0	1	2	3
Age[b]	<60	60–79	≥80	
Shock[b]	No shock (systolic blood pressure ≥100, pulse <100)	Tachycardia (systolic blood pressure ≥100, pulse ≥100)	Hypotension (systolic blood pressure <100)	
Co-morbidity[b]	No major co-morbidity		Cardiac failure, ischaemic heart disease, any major co-morbidity	Renal failure, liver failure, disseminated malignancy
Diagnosis[c]	Mallory–Weiss tear, no lesion identified and no stigmata of recent haemorrhage	All other diagnoses	Malignancy of upper gastrointestinal tract	
Major stigmata of recent haemorrhage[c]	None or dark spot only		Blood in the upper gastrointestinal tract, adherent clot, visible or spurting vessel	

[a] The total score can range from 0 to 11, with a score of 2 representing the clinical cut-off, above which patients are considered to be at high risk of death or rebleeding.

[b] Scores are calculated on admission.

[c] Scores are added after endoscopy.

From Rockall TA, Logan RF, Devlin HB, Northfield TC. Risk assessment after acute upper gastrointestinal haemorrhage. *Gut* . 1996;38(3):316–321.

The Blatchford risk score was derived to predict death and the need for treatment (transfusion, endoscopic treatment and surgery) (see Table 52.2).[12] The total Blatchford score can range from 0 to 23, where a score of 0 is the clinical cut-off above which patients are considered to be at risk of needing an intervention.[7, 12] The full score was validated internally on 197 patients and performed better than the Rockall score in predicting the need for treatment.[12] A multicentre international study showed the Glasgow Blatchford scores had the highest discriminative ability at predicting 30-day mortality from upper gastrointestinal bleeding compared to the Rockall and other scoring systems.[13]

Table 52.2

A total score can range from 0 to 23. A score of 0 is the clinical cut-off, above which patients are considered to be at risk of needing an intervention.

From Blatchford O, Murray WR, Blatchford M. A risk score to predict need for treatment for upper gastrointestinal haemorrhage. *Lancet* . 2000;356(9238):1318–1321.

Pharmacological Treatment

Acid-suppressing drugs such as proton pump inhibitors (PPIs) and H_2-receptor antagonists are very effective drugs to promote peptic ulcer healing. An acidic environment impairs platelet function and haemostasis; therefore reducing the secretion of gastric acid optimises platelet aggregation and clot formation. [14]

Pharmacological control without endoscopic haemostasis is inadequate and there is a lack of evidence to support pre-endoscopic treatment with PPIs, with no evidence of benefit in terms of mortality, rebleeding or need for surgery. [15, 16] Pre-endoscopic use of proton pump inhibitors in acute upper gastrointestinal bleeding is not recommended by the National Institute for Health and Care Excellence (NICE). [17] Patients with non-variceal upper gastrointestinal bleeding and stigmata of recent haemorrhage shown at endoscopy should be offered PPIs. [15, 16, 18] There is evidence that potent acid suppression using intravenous PPIs post-endoscopy results in reduced rebleeding, reduced need for surgery, and reduced need for repeated endoscopic treatment. [15, 16] PPIs should be recommended in high-risk peptic ulcer bleeding patients as an adjuvant to endoscopic therapy and a combination of endoscopic and pharmacological therapy offers the best therapy for ulcer bleeding patients.

Endoscopy

Endoscopy is the investigation of choice, with potential therapeutic benefit, and should be offered within 24 hours of presentation to the hospital to provide optimal clinical outcomes.[19] Early endoscopy and endoscopic therapy (<24 hours from admission) are associated with a reduced transfusion need, a reduction in rebleeding, a lower need for surgery and a reduction in length of stay compared to patients receiving later endoscopy.[19-21] In patients with acute upper gastrointestinal bleeding who were at high risk for further bleeding or death, endoscopy performed within 6 hours after gastroenterology consultation was not associated with lower 30-day mortality than endoscopy performed between 6 and 24 hours after consultation.[22] Endoscopy allows identification of the site and nature of bleeding and treatment can be provided endoscopically. Endoscopy may induce serious hypoxia in patients with cardiorespiratory disease, and careful supervision with continuous monitoring of blood pressure, pulse and oxygen saturation with a pulse oximeter is mandatory.

High-Risk Lesions

Most patients with acute upper gastrointestinal haemorrhage stop bleeding spontaneously and have an uneventful recovery. No specific intervention is required in these patients. Endoscopic haemostasis should be used in patients with a high risk of persistent or recurrent bleeding. Stigmata of haemorrhage found during endoscopy are integral to the Rockall scoring system and are important predictors of recurrent bleeding.[7] These stigmata include localised active bleeding (i.e. pulsatile and arterial spurting or simple oozing), an adherent blood clot, a protuberant vessel or a flat, pigmented spot on the ulcer base (Table 52.3).[20,23,24] Only high-risk lesions (active arterial bleeding, non-bleeding visible vessels or an adherent blood clots) should be treated endoscopically since only these are at risk of further bleeding.[20,23,24] The proximal postero-inferior wall of the duodenal bulb and the high lesser curve of the stomach are common sites for severe recurrent bleeding, probably owing to their respective large arteries (gastroduodenal and left gastric arteries).

Table 52.3

Stigmata of haemorrhage and risk of recurrent bleeding in peptic ulcers

STIGMATA OF HAEMORRHAGE	% RECURRENT BLEEDING
Spurter or oozer	85–90
Protuberant vessel	35–55
Adherent clot	30–40
Flat spot	5–10
None	5

Adrenaline (epinephrine) injection

Endoscopic injection of adrenaline (1:10,000 dilution) into and around the ulcer bleeding point is an effective, cheap, portable and easy-to-learn method of haemostasis. [25] Injection into ulcers with adherent blood clots significantly reduces rebleeding from approximately 35%–10%. [23, 26] Debate exists as to whether the haemostatic effect is a result of local tamponade by the volume injected or vasoconstriction by adrenaline, or a combination of both. When different volumes of adrenaline solution 1:10,000 are compared, there were no significant differences in the rate of initial haemostasis between three groups with 20, 30 and 40 mL of endoscopic injections, but the rate of peptic ulcer perforation was significantly higher in the group receiving 40 mL adrenaline, and the rate of recurrent bleeding was significantly higher in the 20 mL adrenaline group (20.3%) than in the 30 mL (5.3%) and 40 mL (2.8%) adrenaline groups. [27] Absorption of adrenaline into the systemic circulation has been documented but without any significant effect on the haemodynamic status of the patient. [28]

Thermal

This method uses direct pressure and heat energy (heater probe) or electrocoagulation (bipolar coagulation probe [BICAP]) to control ulcer bleeding. The depth of tissue injury induced by these devices is minimal, as the bleeding vessel is tamponaded prior to coagulation. The overall efficacy of the heater probe and BICAP probe methods are comparable to the adrenaline injection, [28] and any complications, including mucosal perforation, are rare. [29], [30]

Mechanical

The advantage of haemoclips over thermocoagulation is that there is no tissue injury induced and hence the risk of perforation is reduced. Studies comparing haemoclips with injection and thermocoagulation have shown favourable results for endoscopic clipping, including higher definitive haemostasis and reduced rebleeding compared to injection, and comparable efficacy to thermocoagulation. [31-33] However, the application of haemoclips in certain sites, for example lesser curve, gastric fundus and posterior wall of the duodenum, is technically difficult.

Combination

Combinations of endoscopic treatments, comprising an injection of adrenaline coupled with either a thermal or mechanical therapy, are superior to the use of a single modality treatment, resulting in decreased rebleeding and emergency surgery rate without increased risk of complications. [33], [34] Studies have shown each endotherapy technique is comparable in achieving haemostasis with the exception of adrenaline. Therefore adrenaline should not be offered as monotherapy. [35]

Repeat endoscopy

Rebleeding is apparent in cases of ongoing haematemesis, melena, haemoglobin drop (>20 g/L) or haemodynamic instability. Repeat endoscopy is indicated. Furthermore, repeat endoscopy could be performed within 24 hours when initial endoscopic treatment was considered sub-optimal due to difficult access, poor visualisation or technical difficulties. Repeat endoscopy reduces the risk of rebleeding [33], [36] and should be considered for patients in whom rebleeding is likely to be life threatening.

For patients who rebleed after endoscopic therapy, they should be considered for repeat endoscopic treatment, selective arterial embolisation or surgery. In a study investigating the best salvage treatment for patients with recurrent bleeding after endoscopic therapy, repeat endoscopic therapy was found to be comparable to surgery in securing haemostasis, with similar 30-day mortality and transfusion requirements; however, morbidity was significantly higher after surgery compared to repeat endoscopy. [37]

Angiography

Angiography and angioembolisation is a diagnostic and therapeutic options for gastrointestinal haemorrhage. Angiography alone can be helpful as a diagnostic tool to locate the site of bleeding for subsequent radiological or surgical intervention. In cases of the bleeding being very brisk and obscuring the endoscopic view, angiography may help to identify the source of bleeding. Once the bleeding point is identified, angiography may be also used to embolise the bleeding point with simultaneous superselective coil transcatheter embolisation. Agents can be delivered radiologically to occlude the vascular supply, such as coils or particles, with the aim of reducing blood flow to the bleeding vessel and thereby reducing perfusion pressure and enabling clot formation at the bleeding site. [38] Studies reporting on the use of angiography and embolisation have demonstrated high rates of technical success, low rebleeding rate and low complication rates. [39-42] An important complication of embolisation is the risk of ischaemia that can be caused by reducing the blood flow to the organ supplied by the target blood vessel (e.g. hepatic/splenic infarction and duodenal ischaemia) and also the risk of embolisation of an inappropriate vessel. [39-42] Angiography may be preferred to surgery in patients with multiple co-morbidities where there is a high risk of postoperative morbidity and mortality, and its use is well established in managing haemorrhage secondary to peptic ulcer disease in patients who are at high risk for surgery. [43], [44]

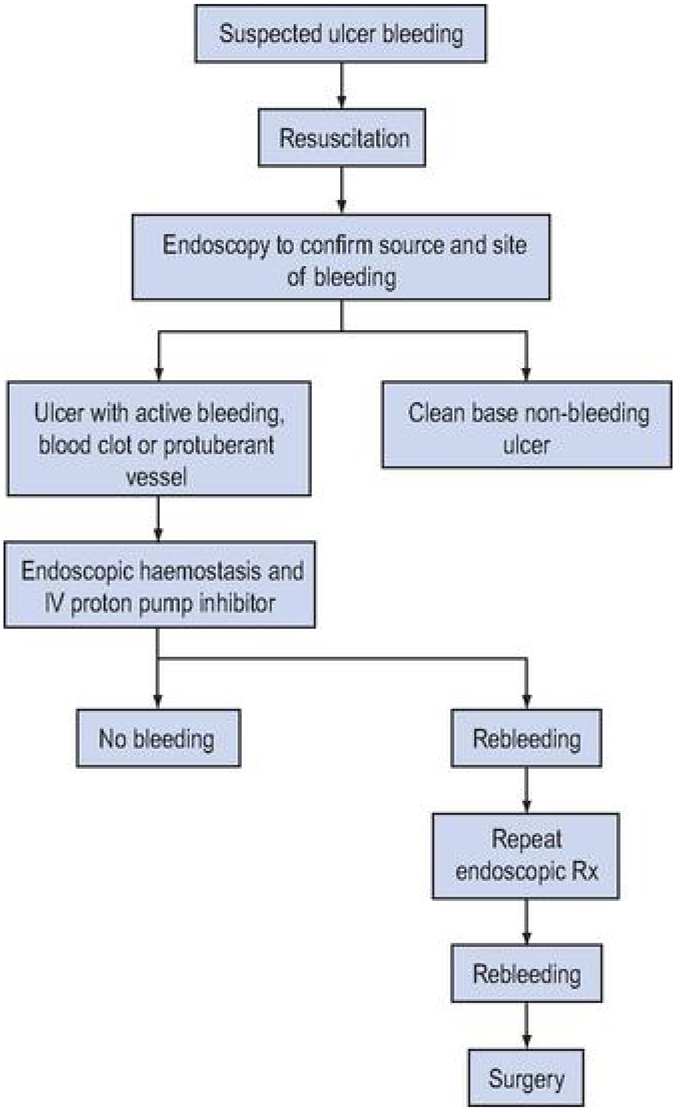
Surgery

Surgery remains the definitive method of stopping haemorrhage, but there is little agreement on the exact indications and best timing for surgical intervention. These issues are even less clear now that endoscopic treatment and angioembolisation are so effective. Accordingly, good cooperation among intensivists, gastroenterologists, radiologists and surgeons is essential. Indications for surgery can be:

- arterial bleeding that cannot be controlled by endoscopic haemostasis or angioembolisation
- massive transfusion (i.e. a total of 6–8 units of blood) required to maintain blood pressure
- recurrent clinical bleeding after initial success in endoscopic haemostasis
- evidence suggestive of gastrointestinal perforation.

Surgical procedures include underrunning of the ulcer, underrunning plus vagotomy and drainage and various types of gastrectomy. The overall mortality of emergency surgery for gastrointestinal bleeding is about 15%–20%. Early surgery should be considered in patients with hypovolaemic shock and/or large peptic ulcers with protuberant vessels.

A protocol to manage bleeding peptic ulcer is shown in Fig. 52.1 .[45]



Suspected ulcer bleeding
Resuscitation
Endoscopy to confirm source and site of bleeding
Ulcer with active bleeding, blood clot or protuberant vessel
Clean base non-bleeding ulcer
Endoscopic haemostasis and IV proton pump inhibitor
No bleeding
Rebleeding
Repeat endoscopic Rx
Rebleeding
Surgery

The flowchart details a medical protocol for suspected ulcer bleeding. At the top, the process begins with a suspected ulcer bleed. The first step involves endoscopy to confirm the source and site of the bleed after performing resuscitation. The flowchart then branches into two paths. If an ulcer with active bleeding, blood clot, or visible vessel is found, the left path proceeds with intravenous proton pump inhibitor administration or endoscopic haemostasis, leading to no bleeding. If a clean base non-bleeding ulcer is identified, the right path continues to cleaning base non-bleeding ulcer. If rebleeding occurs, which prompts a repeat of endoscopy treatment. If rebleed persists, the final step directs to surgery.

FIG. 52.1 Management of peptic ulcer bleeding. *IV,* Intravenous; *Rx,* treatment.

Prevention of Rebleeding

Acid Suppression

Acid suppression therapy should be given to patients at high risk of rebleeding and to patients undergoing endoscopic therapy to achieve haemostasis, to maintain intragastric pH above 6 to stabilise clots and prevent rebleeding. [14] A meta-analysis concluded that in ulcer bleeding, PPIs reduce the risk of rebleeding and the need for surgery or repeat endoscopy, and decrease mortality among high-risk patients. [18]

Tranexamic Acid

Tranexamic acid did not reduce death from GI bleeding in a large randomised control trial. [46] Therefore its use is no longer recommended in the context of gastrointestinal bleeding. [5, 6, 47]

Non-Steroidal Anti-Inflammatory Drugs

NSAID use and *Helicobacter pylori* (*H. pylori*) infection increase the risk of upper gastrointestinal bleeding, with this risk increasing further when both factors are present. [48] The elderly and patients with a history of peptic ulcer could benefit the most from a reduction in NSAID gastrotoxicity. Clinical factors reported to increase the risk of developing NSAID-associated upper gastrointestinal complications include a history of ulcer or gastrointestinal bleeding, increasing age, concomitant anticoagulation or corticosteroid therapy and high-dose NSAID use. [49]

Helicobacter Pylori

Eradication of *H. pylori* results in reduced recurrence of uncomplicated peptic ulcer disease [40] and prevents recurrent bleeding. [50], [51] Treatment of *H. pylori* infection is more effective than antisecretory non-eradicating therapy in preventing recurrent bleeding from peptic ulcer. [46] The rapid urease test for *H. Pylori* is quick, easy to perform and inexpensive, but PPI therapy is associated with false-negative rapid urease results. Therefore when negative for this test, additional biopsies should be examined histologically, and mucosal biopsies should be obtained from the antrum and body of the stomach at the initial endoscopy prior to commencing PPI therapy. [52] For those patients who test positive for *H. pylori* , eradication therapy should be prescribed.

Acute Stress Ulceration

Acute stress ulceration is associated with shock, sepsis, burns, multiple traumas, head injuries, spinal injuries and respiratory, renal and hepatic failure. Bleeding may be occult or overt, from ‘coffee-ground’ aspirates to frank haemorrhage. Lesions are most commonly seen in the gastric fundus and range from mild erosions to acute ulcerations. The exact mechanism leading to acute mucosal erosion/ulceration in critically ill patients is still unclear. Hypoxia and hypoperfusion of the gastroduodenal mucosa are probably the most important factors, but haemodynamic instability, respiratory failure and coagulopathy are also strong independent factors in critically ill patients. The reported incidence of stress-related mucosal bleeding in ICU patients ranges from 8% to 45%. [53] It has been declining in the last decade as a result of highly effective management of hypotension and hypoxaemia in the ICU. Prophylactic use of acid-suppressing drugs is recommended by NICE for primary prevention of upper gastrointestinal bleeding in patients admitted to critical care. [17]

Prophylactic treatment for acute stress ulceration, given in the oral form of the drug if possible, aims for gastric alkalinisation (gastric pH > 3.5), with the rationale that gastric acidity is the main cause of stress ulceration. [53] The incidence of stress ulceration appears to be lower with prophylactic gastric alkalinisation than with placebos, although an improvement in survival has not been shown.[54, 55] Concerns have included gastric bacterial overgrowth and associated nosocomial pneumonia, but these have not been substantiated by existing data.

- Antacids – Antacids can maintain gastric alkalinisation and contain magnesium, aluminium, calcium or sodium. Complications may arise from excessive intake of these minerals, and bowel stasis and diarrhoea can also be problems.
- Sucralfate – Sucralfate is effective in increasing mucus secretion, mucosal blood flow, and local prostaglandin production. It promotes ulcer healing and mucosal resistance against acid and pepsin (i.e. it is cytoprotective). As it does not alter gastric pH, Gram-negative bacterial colonisation of gastric juice is less likely. The incidence of nosocomial pneumonia may be less with sucralfate than with antacids or H_2-receptor antagonists, but this is debatable and is offset by the potential risk of aspiration.[55]
- H_2-receptor antagonists – These drugs suppress acid secretion by competing for the histamine receptor on the parietal cell.
- PPIs – These drugs block the final common pathway of acid secretion by the parietal cell, namely the proton pump. They were shown to protect critically ill patients requiring ventilation from the development of stress-related mucosal bleeding from the upper gastrointestinal tract.[55] All PPIs can be given as oral medications. Omeprazole and pantoprazole are also available in intravenous form for those who cannot be fed orally.

Reasonable doubt remains the best pharmacological agent for stress ulcer prophylaxis in critically ill patients. A large randomised controlled trial (RCT) of H_2-receptor antagonist versus PPI usage in mechanically ventilated patients demonstrated a lower rate of clinically significant upper GI bleeding in the PPI group (1.3% vs. 1.8%, Risk Ratio 0.73, 95% confidence interval 0.57–0.92, $P = .009$). However, the 90-day mortality rate was 18.3% in the PPI group versus 17.5% in the H_2-receptor antagonist group ($P = .054$). Of note, there was significant crossover usage of the two types of drugs despite randomisation.[56]

A network analysis of 57 RCTs of stress ulcer prophylaxis in critically ill patients demonstrated that PPIs are likely to be more effective at preventing clinically important GI bleeding (Odd ratio 0.38, 95% confidence interval 0.10–0.60). However, PPIs were associated with higher rates of pneumonia. The evidence base was heterogeneous and leaves some debate for the most effective method for stress ulcer prophylaxis.[57], [58]

Appropriate selection of patients for stress ulcer prophylaxis is key in view of the potential harm of over-use. Even for patients at high risk, the number needed to treat is possibly larger than previously thought. Given the possible adverse effects, widespread use—even in high-risk patients—may not achieve a net benefit. For low-risk patients in the ICU in the absence of a clear indication, it may confer a net harm.[59]

Variceal Bleeding

Varices are abnormal, dilated veins at the junction between the portal and systemic venous systems, usually in the oesophagus (oesophageal varices, 90%) and less frequently in the stomach (gastric varices, 8%) or other sites (ectopic varices, 2%). Acute variceal bleeding is a serious complication of portal hypertension related to liver disease, with a high mortality. The degree of liver failure, using the Child–Pugh classification, is the most important prognostic factor for early rebleeding and survival.[60] Variceal bleeds are associated with 20% six-week mortality.[61] The size of the varices and their propensity to bleed is directly related to the portal pressure, which, in most cases, is directly related to the severity of the underlying liver disease.

Resuscitation

Immediate resuscitation with whole blood and fluid is mandatory. Over-transfusion may cause a rebound increase in portal pressure (with a consequent increased risk of rebleeding) and must be avoided. Fresh frozen plasma and platelet transfusion may be indicated. A nasogastric tube is often inserted for the removal of blood (and also for drug administration). However, during insertion, trauma to the varices could cause additional bleeding. Lactulose (15–30 mL every 4–6 hours) can be given to prevent or correct hepatic encephalopathy. When the patient is haemodynamically stable, upper gastrointestinal endoscopy should be performed to identify the source of bleeding.

Pharmacological Treatment

Vasopressin

Vasopressin used to be the most widely used agent to reduce portal blood pressure and control variceal bleeding. Adverse effects of vasopressin such as cardiac ischaemia (in about 10% of patients) and worsening coagulopathy (by release of plasminogen activator) have discouraged the use of this drug in recent years. Terlipressin, a triglycyl synthetic analogue of vasopressin, has a longer half-life and fewer cardiac side effects and appears more effective and safe when used in combination with glyceryl trinitrate.[62] Terlipressin used in the treatment of acute variceal haemorrhage results in a significant decrease in mortality.[63] When terlipressin was used specifically before endoscopy, it resulted in better bleeding control and decreased mortality, suggesting that terlipressin may be given prior to endoscopic diagnosis to patients suspected of variceal haemorrhage.[64] Terlipressin given after endoscopic diagnosis of acute variceal haemorrhage resulted in improved haemostasis.[65], [66]

Somatostatin

Infusion of somatostatin and its analogues (octreotide and vapreotide) reduces portal blood pressure and azygos blood flow. They are safe and effective vasoactive agents to be used in acute variceal bleeding.[67] Although they do not reduce mortality, they result in a decrease in the amount of blood transfusion required and in the number of patients failing initial haemostasis.[68] When somatostatin was used before endoscopy, it resulted in improved haemostasis, but no reduction in rebleeding or mortality.[69] Somatostatin given after endoscopic confirmation of variceal haemorrhage made no difference in rebleeding or mortality.[70] The combination of somatostatin, octreotide or vapreotide, with endoscopic therapy was superior to endoscopic therapy alone, with improved haemostasis and decreased rebleeding, although there was no survival benefit.[71]

Antibiotics

Prophylactic antibiotic use in patients with cirrhosis and upper gastrointestinal bleeding was found to result in significantly reduced bacterial infections, all-cause mortality, bacterial infection mortality, rebleeding events and hospitalisation length.[72]

Propranolol

Propranolol monotherapy used for secondary prevention of variceal haemorrhage results in decreased risk of mortality and rebleeding.[73] The combination of beta blocker and nitrate is superior to beta-blocker therapy alone and of equal efficacy to variceal band ligation.[74,75] Variceal band ligation combined with a beta blocker is recommended as secondary prevention for oesophageal variceal haemorrhage. In patients unsuitable for variceal band ligation, a combination of non-selective beta blockers and nitrate would be the alternative.

A retrospective analysis of 271 consecutive patients presenting with variceal bleeding in the context of cirrhosis with ascites, treated with beta blocker in combination with endoscopic variceal ligation or endoscopic variceal ligation alone, showed a significantly higher mortality rate in the beta blocker group. This raises the safety of beta blocker use in this patient cohort.[76] However, in a retrospective populational study from Korea, low-dose propranolol was associated with lower mortality and rebleeding rates when used as secondary prevention after variceal bleeding in patients with large-volume ascites.[77]

Clearly, there remains significant debate regarding the most effective pharmacological agents in the management of variceal bleeding. A meta-analysis of 21 trials comparing vasopressin and somatostatin did not show a significant difference in mortality, bleeding control or rebleeding rates. However, there were significantly higher rates of adverse events associated with the use of terlipressin and vasopressin (relative risk 2.39, 95% confidence interval 1.58–3.63).[78]

A recent pharmacodynamic randomised control trial of terlipressin versus octreotide showed both were effective in reducing hepatic venous pressure gradient (52.8% vs. 44.8%, $P = .524$). Terlipressin had significantly higher response rates at 30 minutes compared to octreotide. The response rates were also higher in patients with alcoholic liver cirrhosis, although the numbers in this subgroup were very small. Terlipressin was more often associated with decreased heart rate and increased mean arterial blood pressure.[79]

Therefore bespoke assessment and management are required when managing patients with variceal bleeding.

Endoscopic Variceal Ligation

Endoscopic variceal ligation is performed with rubber bands mounted on the banding device at the tip of the endoscope, which is released to strangulate the bleeding varices. Studies comparing endoscopic variceal ligation with endoscopic sclerotherapy showed that the technique is as effective as injection sclerotherapy in acute bleeding with fewer procedure-related complications, possibly because there is no tissue chemical irritation. A meta-analysis demonstrated that variceal band ligation therapy was superior to sclerotherapy in terms of rebleeding, all-cause mortality, and death due to bleeding in patients with bleeding oesophageal varices.[80] A further RCT demonstrated better control of oesophageal variceal bleeding with ligation than sclerotherapy, and complications were found to be greater in the sclerotherapy group, particularly in regard to sepsis and oesophageal ulceration.[81] Based on the current evidence, patients with confirmed oesophageal variceal haemorrhage should undergo endoscopic variceal band ligation rather than injection sclerotherapy.

Endoscopic Sclerotherapy

During endoscopy, sclerosants or thrombin can be injected directly into the variceal columns (intravariceal injection) or into the mucosa adjacent to the varices (paravariceal injection) to cause venous thrombosis and inflammation, and tissue fibrosis. A commonly used sclerosant is cyanoacrylate. Possible complications include ulcer formation, fever, chest pain and mediastinitis. RCTs comparing the efficacy and complications of cyanoacrylate injection versus banding ligation for the management of bleeding gastric varices demonstrated better haemostasis, decreased rebleeding, and lower amount of blood transfusions required with injection treatment compared to banding.[82], [83] Bleeding gastric varices continuous with oesophageal varices extending 2–5 cm along the lesser curve of the stomach can be managed with band ligation.[84]

A 2019 meta-analysis demonstrated the evidence for endoscopic ligation and sclerotherapy consists of heterogenous studies most of which were conducted before 2010. There appeared to be a superiority of ligation to sclerotherapy, albeit with caveats due to the quality of the evidence.[85]

Balloon Tamponade

Balloon tamponade is a temporary measure that can control massive variceal bleeding which does not respond to endoscopic therapy. Variceal bleeding can be controlled by exerting pressure directly on the bleeding point using a balloon. The Sengstaken–Blakemore tube has been replaced by the four-lumen Minnesota tube, which allows aspiration of gastric and oesophageal contents. More recently, a self-expanding Danis stent has emerged as a possible alternative to balloon tamponade.

Inflation of the gastric balloon (by 250–350 mL of water) is often sufficient to stop the bleeding by occluding the feeding veins to the oesophageal varices. If bleeding continues, the oesophageal balloon can be inflated by air and kept at a pressure of 50–60 mm Hg (6.7–8.0 kPa). Rates of haemostasis associated with balloon tamponade are reported to be 80%–95% in patients with either oesophageal or gastric varices.[86] Duration of using balloon tamponade should be limited to 24 hours to avoid tissue pressure necrosis. Other complications of balloon tamponade include pneumonia, oesophageal tears and discomfort. Because of available effective pharmacological and endoscopic therapies with lower complication rates, balloon tamponade should be used only in exceptional cases when these therapies fail to control bleeding, and as a temporising measure before repeat endoscopy or transjugular portosystemic shunt.[87], [88]

More recently, oesophageal stenting has been proposed as an alternative to balloon tamponade in cases of refractory variceal bleeding.[89]

Transjugular Intrahepatic Portosystemic Shunt

Transjugular intrahepatic portosystemic shunt (TIPS) can be administered once the patient has been stabilised and is the definitive treatment of choice for uncontrolled variceal haemorrhage. Using a transjugular approach, a catheter is inserted into the hepatic vein and advanced under fluoroscopic guidance into a branch of the portal vein. [90] By means of a guidewire and dilators, a self-expandable metal stent is introduced to create an intrahepatic portosystemic shunt. This procedure significantly reduces portal blood pressure and thus bleeding from varices. Major complications include intra-abdominal haemorrhage and stent occlusion. Hepatic encephalopathy has been reported in 25%–60% of patients. Nevertheless, this is an effective salvage treatment for uncontrolled variceal bleeding. Meta-analysis comparing TIPS with endoscopic therapy showed that the former has improved haemostasis but at the cost of increasing the risk of hepatic encephalopathy. [91] TIPS should be reserved for the subset of patients who continue to bleed or develop recurrent bleeding after endoscopic therapy. Unlike shunt surgery, TIPS will not reduce the chance of future liver transplantation. A meta-analysis comparing portosystemic shunts (TIPS and surgical shunts) versus endoscopic therapy demonstrated a reduction in the rate of rebleeding with shunt therapy, but this was at the cost of an increased incidence of chronic hepatic encephalopathy with no difference in mortality. [92]

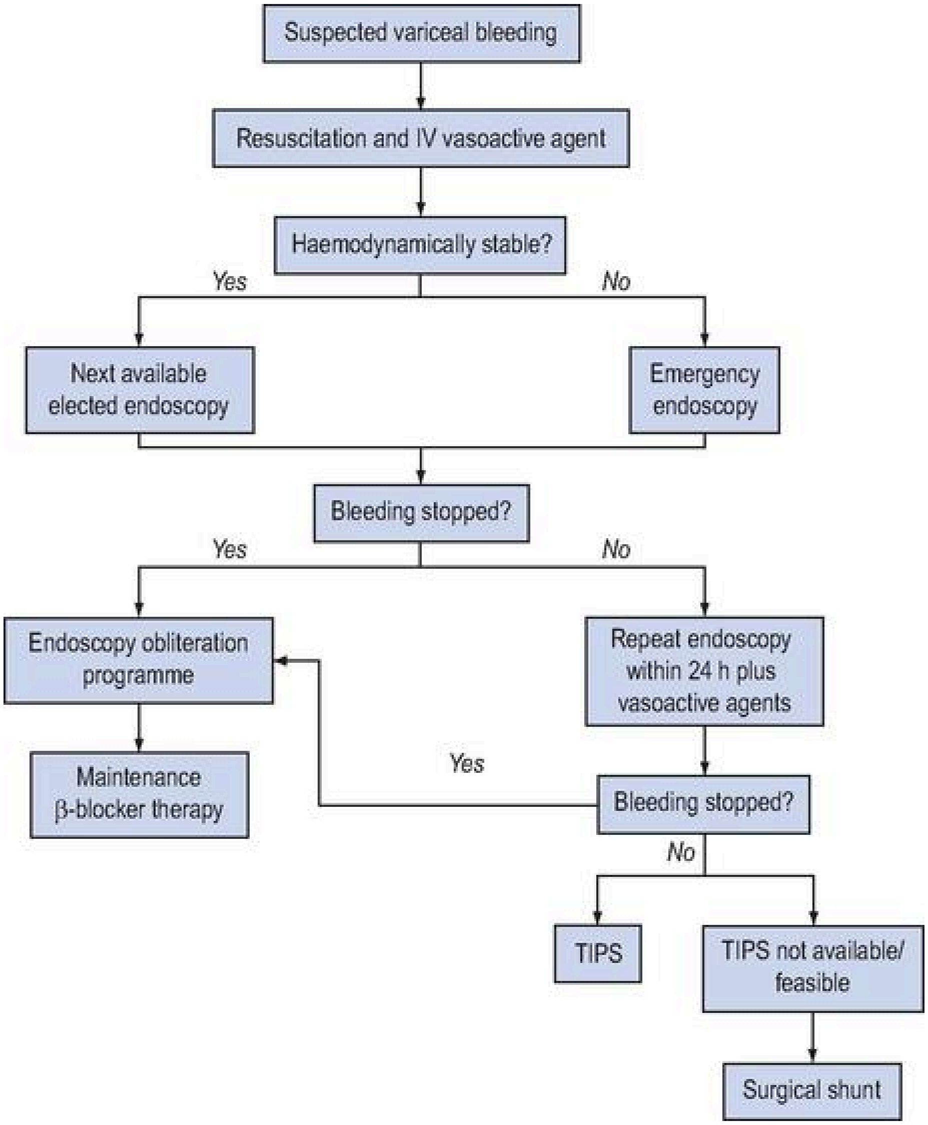
Surgery

Surgical treatments for variceal bleeding include direct devascularisation of the lower oesophagus plus the proximal stomach and a variety of surgical shunts. The role of surgery has diminished since the advent of endoscopic treatment and TIPS. [93] Surgery is now used as a second-line treatment when bleeding continues or recurs after two sessions of injection sclerotherapy or banding ligation. As a last resort, staple transection of the oesophagus and portocaval shunt surgery can be offered, providing specialist expertise is available. Even with successful control of bleeding, long-term survival is not significantly improved.

Hepatic encephalopathy is one of the major complications of shunting operations. [92] Higher shunt dysfunction and reintervention were observed in

TIPS patients compared to those receiving a distal splenorenal surgical shunt operation. [92] Expectations that the Warren distal splenorenal shunt will preserve antegrade portal flow and avoid accelerated deterioration of liver function have not been realised. The Warren shunt is technically more difficult, especially if performed as an emergency. Choice of surgery should be carefully made in those who are potential transplant candidates, as it may complicate subsequent surgery.

A protocol to manage variceal bleeding is shown in Fig. 52.2 .



Suspected variceal bleeding
Resuscitation and IV vasoactive agent
Haemodynamically stable?
Yes
No
Next available elected endoscopy
Emergency endoscopy
Bleeding stopped?
Yes
No
Endoscopy obliteration programme
Repeat endoscopy within 24 h plus vasoactive agents
Yes
Maintenance β-blocker therapy
Bleeding stopped?
No
TIPS
TIPS not available/ feasible
Surgical shunt

The flowchart outlines the management protocol for suspected variceal bleeding. The process starts with identifying suspected variceal bleeding, followed by resuscitation and intravenous vasoactive agent administration. The next decision point assesses if the patient remains haemodynamically stable. If yes, the path leads to elective endoscopy. If no, emergency endoscopy occurs. After endoscopy, the flowchart evaluates if bleeding has stopped. If bleeding stops, the path proceeds to endoscopy obliteration programme and maintenance beta blocker therapy. If bleeding does not stop, the flowchart checks for transjugular intrahepatic portosystemic shunt availability. If available, transjugular intrahepatic portosystemic shunt occurs within twenty four hours with vasoactive agents. If a transjugular intrahepatic portosystemic shunt is not available, the path leads to surgical shunt.

FIG. 52.2 Management of variceal haemorrhage. *IV,* Intravenous; *TIPS,* transjugular intrahepatic portosystemic shunt.

Lower Gastrointestinal Bleeding

Clinical Presentation

Common causes of lower gastrointestinal bleeding include diverticular disease, vascular malformations (angiodysplasia), ischaemic colitis, haemorrhoids, inflammatory bowel disease (e.g. ulcerative colitis and Crohn’s disease), post-polypectomy bleeding, colonic polyps, carcinoma and radiation enteropathy. Haematochezia (bright red blood) is the most common presentation of lower gastrointestinal bleeding. However, bleeding from the small intestine and caecum/right colon may also present as melaena (black, tarry stools). Abdominal pain preceding a massive bleeding episode suggests either ischaemia or inflammatory bowel disease. Painless massive bleeding is common in diverticulosis, angiodysplasia or from a Meckel diverticulum. In a patient with portal hypertension, haemorrhoids may present with massive haematochezia.

Risk factors associated with poor outcomes in patients presenting with acute lower gastrointestinal bleeding include being an inpatient, older age (>60 years), evidence of acute haemodynamic instability at presentation (tachycardia, hypotension and syncope), ongoing bleeding, evidence of gross rectal bleeding, significant co-morbidity, specific drugs such as aspirin or NSAIDs, an elevated creatinine, and anaemia (initial haematocrit

≤35%)[94-98] Diverticular disease is the commonest cause of lower gastrointestinal bleeding, accounting for 23%–48% of cases, and with a 9% chance of recurrence at 1 year and 25% at 4 years.[99]

Haemodynamic instability can be assessed using the shock index (heart rate divided by systolic blood pressure). Patients with a shock index >1 are considered unstable. These patients warrant expedient resuscitation, investigation and treatment.[6]

In stable patients (shock index <1), the Oakland score can be used to categorise minor or major lower gastrointestinal bleeding (Table 52.4).[100] For example patients presenting with minor self-terminating bleeds (Oakload score ≤8) would not require hospital admission.

Table 52.4

Variables comprising the Oakland score

Predictor	Score component value
Age	<40: 0 40–69: 1 >70: 2
Gender	Female: 0 Male: 1
Previous lower gastrointestinal bleed admission	No: 0 Yes: 1
Rectal examination finding	No blood: 0 Blood: 1
Heart rate	<70: 0 70–89: 1 90–109: 2 >110: 3 >110:
Systolic blood pressure (mm Hg)	<90: 5 90–119: 4 120–129: 3 130–159: 2 >159: 0
Haemoglobin (g/L)	<70: 22 70–89: 17 90–109: 13 110–129: 8 130–159: 4 >159: 0

Patient scoring >8 are categorised as major bleed and would benefit from hospital admission.

From Oakland K, Guy R, Uberoi R, et al. Acute lower GI bleeding in the UK: patient characteristics, interventions and outcomes in the first nationwide audit. *Gut* . 2018;(67):654–662.

Investigations

Localisation of the site and determination of the cause of bleeding in acute colonic haemorrhage allows treatment to be appropriately focused. Haemorrhoids and rectal tumours can be identified by proctosigmoidoscopy, which should always be performed. Haematochezia associated with haemodynamic instability may be indicative of an upper gastrointestinal bleeding source and thus warrants an upper endoscopy. When both proctosigmoidoscopy and gastroscopy are negative, the lower gastrointestinal tract should be examined by colonoscopy, angiography or radionuclide scan.

Colonoscopy

Colonoscopy should be the initial diagnostic procedure for patients presenting with stable acute lower gastrointestinal bleeding. [101] The endoscopist should intubate the terminal ileum to rule out proximal blood suggestive of a small bowel lesion. The colonic mucosa should be carefully inspected during colonoscopy with aggressive attempts made to wash residual stool and blood to identify the bleeding site. [102] Visualisation is often unsatisfactory due to the dark discolouration of blood, and colonoscopy may yield better results after adequate colon preparation once bleeding has stopped. In studies of urgent colonoscopy without oral or rectal preparation, caecal intubation rates are low (55%–70%). [103], [104] In addition, colonoscopy should be deferred until patients are haemodynamically stable and upper gastrointestinal bleeding has been excluded by upper endoscopy. [105] Urgent colonoscopy does not seem to be necessary as there is little difference in outcome when compared with elective colonoscopy, although studies support that urgent colonoscopy (defined variably as colonoscopy within 12–24 hours) improves diagnostic and therapeutic yield.[101,105,106] Current guidelines recommend that patients with stable major lower gastrointestinal bleeds should have a colonoscopy on the next available endoscopy list.[8]

Computed Tomography Angiography/Angiography

Computed tomographic angiography and angiography should be considered in high-risk patients with ongoing bleeding who do not respond adequately to resuscitation and who are unlikely to tolerate bowel preparation and colonoscopy. It is also helpful when the view of endoscopy is completely obscured by active haemorrhage or when endoscopy cannot identify the bleeding point. Furthermore, it is helpful in defining abnormal vasculatures including angiodysplasia, arteriovenous malformation and various inherited vascular anomalies (e.g. Rendu–Osler–Weber syndrome, pseudoxanthoma elasticum and Ehlers–Danlos syndrome). Angiography localises a lower gastrointestinal bleeding source in 25%–70% of exams,[107,108] although it relies on active brisk bleeding (more than 0.5 mL/min) to identify the bleeding point. There is no clear evidence for the benefit of colonoscopy over computed tomography angiography. Furthermore, computed tomographic angiography is widely available, easy to perform, and accurate at localising the bleeding site. Therefore it is the preferred initial test in lower gastrointestinal bleeding patients who are unstable.[8]

Radionuclide Scan

A red cell scan (99mTc labelled red blood cells) can localise a bleeding source in 65%–80% of exams and may increase the diagnostic yield of angiography by enabling targeted contrast injection.[109,110] One advantage of the red cell scan is the ability to perform repeated scans after the initial injection of tagged cells, making red cell scans most suitable for the evaluation of intermittent, obscure-overt gastrointestinal bleeding.[109,111]

Management

Conservative

A significant proportion of lower gastrointestinal bleeding (80%–85%) will stop bleeding spontaneously without any specific treatment. [88, 112] The patient should be resuscitated, the coagulation corrected, and any anticoagulation medication withheld. Diverticular disease which is the most common cause of lower gastrointestinal bleeding resolves spontaneously in 75% of cases. [99] NSAIDs should be avoided in patients with a history of acute lower gastrointestinal bleeding, particularly if secondary to diverticulosis or angioectasia. Patients with established cardiovascular disease who require aspirin (secondary prophylaxis) should generally resume aspirin as soon as possible after bleeding ceases, but aspirin for primary prevention of cardiovascular events should be avoided. [102, 103] Dual antiplatelet therapy should not be discontinued in patients with acute coronary syndrome within the past 90 days or coronary stenting within the past 30 days. [113-115] As with all patients with gastrointestinal bleeding on anticoagulants, a multidisciplinary approach involving haematology, cardiology/neurology and gastroenterology should be sought.

Endoscopy

Endoscopic haemostasis therapy should be provided to patients with high-risk endoscopic stigmata of bleeding including active bleeding (spurting and oozing), non-bleeding visible vessels or adherent clots. [116] The endoscopic haemostasis modality used is most often guided by the aetiology of bleeding, access to the bleeding site and the endoscopist's experience with the various haemostatic modalities. Adrenaline injection therapy can be used to gain initial control of an active bleeding lesion and improve visualisation but should be used in combination with a second haemostatic modality, including mechanical or contact thermal therapy, to achieve definitive haemostasis. [105, 106, 116] Bleeding from colonic diverticula can be controlled with endoscopic clips, as clips may be safer in the colon than contact thermal therapy and are generally easier to perform than band ligation, particularly for right-sided colon lesions. [117] Bleeding from vascular anomalies or post-polypectomy can be treated by mechanical (clip) or contact thermal therapy, with or without the combined use of dilute adrenaline injection. [118, 119] Bleeding colonic polyps can be removed by polypectomy or coagulated by thermocoagulation.

Angiography and Angioembolisation

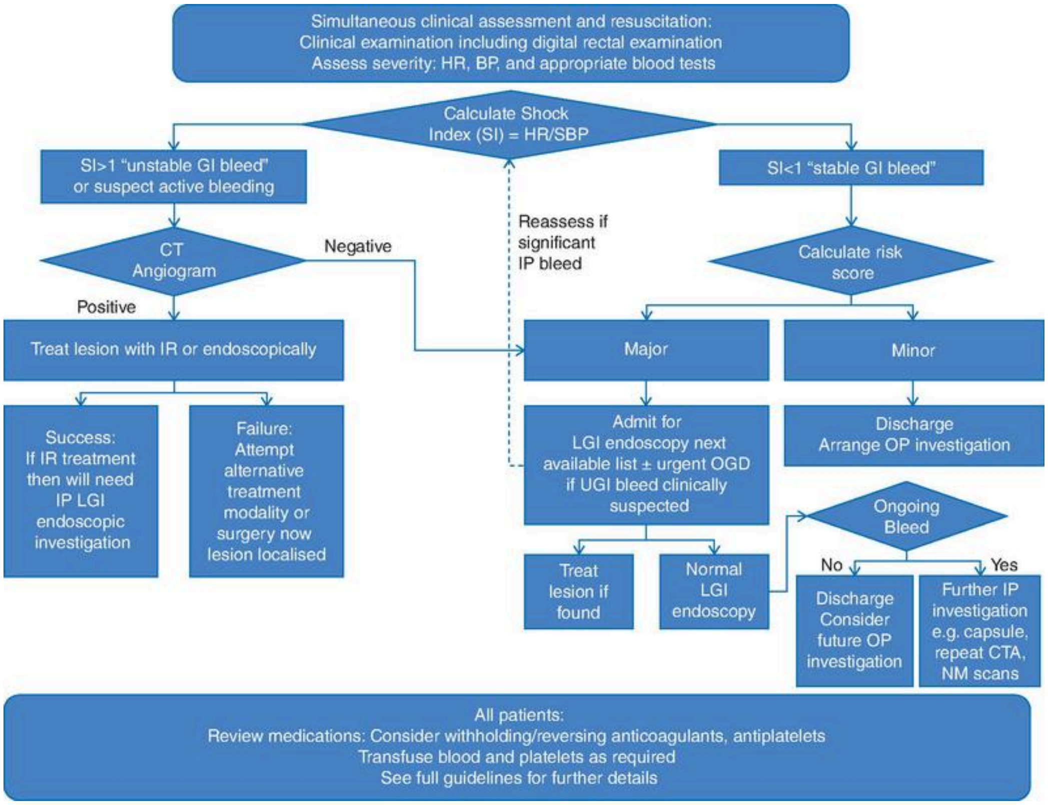
Angiography alone can be helpful as a diagnostic tool to locate the site of bleeding for subsequent radiological or surgical intervention. Once the bleeding point is identified, angiography may be used to embolise the bleeding point with simultaneous superselective coil transcatheter angioembolisation. Studies have shown that angioembolisation is safe and effective in achieving immediate haemostasis, with high technical and clinical success rates (93%–100%), although it has a low risk of bowel ischaemia (7%–24%) and late rebleeding 10%–50%). [107, 120, 121]

Surgery

Surgery for acute lower gastrointestinal haemorrhage should be considered after all other therapeutic options have failed and should take into consideration the extent and success of prior bleeding control measures, severity and source of bleeding and the level of co-morbid disease.

Before surgery, it is important to make all attempts to localise the source of bleeding to avoid continued or recurrent bleeding from an unresected culprit lesion or to avoid unnecessary extensive colonic resection. Current guidelines recommend that no patient should proceed to emergency surgery unless every effort has been made to localise the bleeding by radiological and/or endoscopic modalities, except under exceptional circumstances. On-table endoscopic examination is advisable to localise the bleeding point. Segmental resection of the colon, with its associated risks of morbidity and mortality, is warranted after localisation of the bleeding site. When an obvious and refractory massive lower gastrointestinal bleeding is not identified by endoscopic or angiographic examinations, subtotal colectomy can be offered. [122]

A protocol to manage lower gastrointestinal bleeding is shown in Fig. 52.3 . [8]



Simultaneous clinical assessment and resuscitation:
Clinical examination including digital rectal examination
Assess severity: HR, BP, and appropriate blood tests
Calculate Shock Index (SI) = HR/SBP
SI>1 "unstable GI bleed" or suspect active bleeding
SI<1 "stable GI bleed"
Reassess if significant IP bleed
CT Angiogram
Negative
Positive
Calculate risk score
Treat lesion with IR or endoscopically
Major
Minor
Success: If IR treatment then will need IP LGI endoscopic investigation
Failure: Attempt alternative treatment modality or surgery now lesion localised
Admit for LGI endoscopy next available list ± urgent OGD if UGI bleed clinically suspected
Discharge Arrange OP investigation
Ongoing Bleed
No
Yes
Treat lesion if found
Normal LGI endoscopy
Discharge Consider future OP investigation
Further IP investigation e.g. capsule, repeat CTA, NM scans
All patients:
Review medications: Consider withholding/reversing anticoagulants, antiplatelets
Transfuse blood and platelets as required
See full guidelines for further details

The flowchart details a clinical assessment and resuscitation protocol for gastrointestinal bleed, which includes digital rectal examination. The process begins with simultaneous clinical assessment and resuscitation, calculation of shock index, heart rate, and blood pressure, and assessment shock index score. If a suspected gastrointestinal bleed or active bleeding occurs, a computed tomography angiogram is performed. If positive, the path leads to treatment of the lesion with interventional radiology or endoscopy if the bleeding remains uncontrolled or the lesion cannot be localised endoscopically. If the procedure is a success, a lower gastrointestinal endoscopic investigation is needed. If the procedure is a failure, attempt an alternative treatment modality or surgery now that the lesion is localised. If the computed tomography is negative, the path calculates risk scores. If responses indicate positive bleeding, the bleed severity splits into major or minor categories. Major bleed involves admitting for lower gastrointestinal endoscopy on the next available list or urgent OesophagoGastro-Duodenoscopy if upper gastrointestinal bleeding is clinically suspected. This leads to the following results: treat the lesion if found, or perform a normal lower gastrointestinal endoscopy. If the bleeding is ongoing after endoscopy, further I P investigation, for example, capsule, or repeat CTA, N M scans. If the bleeding has stopped, discharge and consider future outpatient investigation. Minor bleed advises discharge with arrangements for outpatient investigation.

Acute pancreatitis

Aimee Brame

Acute inflammation of the pancreas produces a spectrum of symptoms, which may be mild and self-limiting, or reflect severe disease that rapidly leads to acute respiratory distress syndrome (ARDS), multiple-organ failure and death. In the majority of patients, a treatable underlying cause is identified. Although mild, interstitial, oedematous pancreatitis is more common (80%), it is the more severe form—acute necrotising pancreatitis (ANP)—which accounts for the associated mortality, 17%–21% even in specialist centres. [1-3]

Management of patients with severe ANP is time consuming, labour and resource intensive. Long-term follow-up suggests that, although some survivors suffer permanent exocrine and endocrine insufficiency, most maintain a good quality of life. [4]

Treatment for ANP is essentially, supportive. Numerous putative therapeutic interventions have been tried, but few have provided any objective evidence of clinical benefit.

Aetiology

Gallstone disease (35%–40%) [1] and alcohol (35%) [5] remain the two commonest causes of acute pancreatitis worldwide. Although no discernible cause is found in many of the remaining cases, there are well-established associations with a number of infections, certain drugs, hyperlipidaemias and trauma. See Box 53.1 for a more exhaustive list.

Box 53.1

Aetiology of acute pancreatitis

Excess alcohol ingestion

Biliary tract disease
Idiopathic

Metabolic

Hyperlipidaemia
Hyperparathyroidism
Diabetic ketoacidosis
End-stage renal failure
Pregnancy
Post renal transplant

Mechanical disorders

Post-traumatic, post-operative, post-endoscopic retrograde cholangiopancreatography
Penetrating duodenal ulcer
Duodenal obstruction

Infections

Human immunodeficiency virus, mumps, Epstein–Barr virus, Mycoplasma, Legionella, Campylobacter, ascariasis

Vascular

Necrotising vasculitis–systemic lupus erythematosus, thrombotic thrombocytopenia
Atheroma
Shock

Drugs

Azathioprine, aminosalicylates, sulphonamides, thiazides, furosemide, tetracyclines, oestrogens, valproic acid, metronidazole, pentamidine, nitrofurantoin, erythromycin, tetracyclines, methyldopa, ranitidine and steroids

Toxins

Scorpion venom, organophosphates, methyl alcohol

Scoring: Severity and Mortality

Since 1974 the standard means of documenting the severity of disease and risk of mortality has been by **Ranson** criteria (Box 53.2).[6] These factors were determined following the analysis of just 100 patients with predominantly alcohol-induced pancreatitis using clinical and laboratory data obtained at admission and after 48 hours, the number of positive criteria negatively correlated with the outcome. A decade later these criteria were re-evaluated, and the first eight were found to be most predictive – these are now known as the **Glasgow** criteria or Imrie score. This applies to both alcohol- and non–alcohol-induced pathology.[7]

Box 53.2

Adverse prognostic factors in acute pancreatitis Ranson score

On admission

Age >55 years
White cell count >16,000/mm^3
Glucose 11 mmol/L
Lactate dehydrogenase 400 IU/L

Aspartate transaminase >250 IU/L

Within 48 hours of hospitalisation

Decrease in haematocrit >10%
Increase in blood urea >1.8 mmol/L
Calcium <2 mmol/L
PaO_2 <8 kPa
Base deficit >4 mmol/L
Fluid deficit >6 L

Risk factors	Mortality rate
0–2	<1%
3–4	≅ 15%
5–6	≅ 40%
>6	≅ 100%

Blamey et al.[6] found that only eight variables (not lactate dehydrogenase, base deficit and fluid deficit) were predictive and are often referred to as the Glasgow criteria or Imrie score.

From Yang AL, Vadhavkar S, Singh G, Omary MB. Epidemiology of alcohol-related liver and pancreatic disease in the United States. *Arch Intern Med* . 2008;168(6):649–656.

The Bedside index for severity in acute pancreatitis or **BISAP** score is a bedside scoring system which utilises only five criteria (Box 53.3) and can be calculated with data obtained in the first 24 hours. The system is simpler but remains accurate and reliable when compared with Ranson and Imrie.[8, 9]

Box 53.3

BISAP score [9]

Urea >8.92 mmol/L (>25 mg/dL)
Impaired mental status (disorientation, lethargy, somnolence, stupor or coma)
≥2 SIRS criteria
>60 years
Pleural effusion present
Score 1 point for each criteria
Patients with a BISAP score 0/1 had <1% mortality, 2 = 2%, 3 = 5%–8%, 4 = 13%–19% and 5 = 22%–27%.

The **Atlanta** Symposium developed in 1992 [10] divided the disease into two broad categories, interstitial oedematous (without recognisable tissue necrosis) and acute necrotising (with parenchymal and peripancreatic necrosis). [10] The classification was subsequently revised (2012) and now includes clinical assessment of severity and organ failure (**Modified Marshall score**) and defines terms for describing the local complications of acute pancreatitis (Box 53.4). [11]

Box 53.4

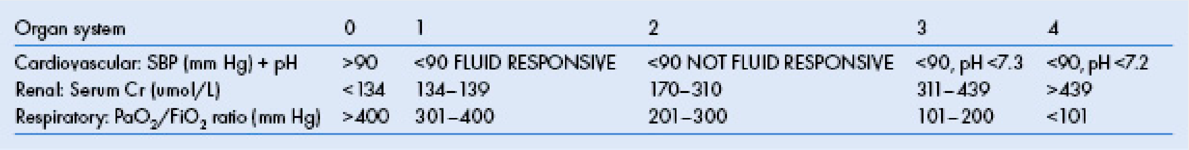
Severity grading for acute pancreatitis – revised Atlanta classification 2012

Grades of severity

- Mild acute pancreatitis
  - No organ failure (Modified Marshall <2)
  - No local or systemic complications
- Moderately severe acute pancreatitis
  - Transient organ failure (resolves <48 hours) ±
  - Local or systemic complications without persistent organ failure

- Severe acute pancreatitis
    - – Persistent single or multiorgan failure (>48 hours)

Modified Marshall Criteria (Score ≥2 indicate organ failure)



Organ system	0	1	2	3	4
Cardiovascular: SBP (mm Hg) + pH	>90	<90 FLUID RESPONSIVE	<90 NOT FLUID RESPONSIVE	<90, pH <7.3	<90, pH <7.2
Renal: Serum Cr (umol/L)	<134	134–139	170–310	311–439	>439
Respiratory: PaO_2/FiO_2 ratio (mm Hg)	>400	301–400	201–300	101–200	<101

Modified from Banks PA, Bollen TL, Dervenis C, et al. Classification of acute pancreatitis–2012: revision of the Atlanta classification and definitions by international consensus. *Gut* . 2013;62:102–111.

The Modified Marshall score uses PaO_2/FiO_2 ratio, serum creatinine and systolic blood pressure to define the presence of organ dysfunction and, hence, severity at 48 hours. [12] The Acute Physiology and Chronic Health Evaluation (APACHE) II scoring system has also been used in predicting the severity of pancreatitis, and can be used daily throughout the patient's hospital admission rather than solely within the first 24–48 hours, thus potentially documenting progress or deterioration. The most predictive factors for mortality include advanced age, the presence of renal or respiratory insufficiency and the presence of shock.

The Management of Severe Pancreatitis

Imaging

Dynamic contrast-enhanced computed tomography (CT) provides the best means of accurately visualising the pancreas and diagnosing pancreatitis and its local complications. It may also be used for guiding percutaneous catheter drainage. [11]

In severe acute pancreatitis, there is a lack of normal enhancement to contrast of all or part of the gland. This is consistent with pancreatic necrosis, defined as diffuse or focal areas of non-viable parenchyma. Microscopically, there is evidence of damage to the parenchymal network, acinar cells and pancreatic ductal system and necrosis of perilobular fat. Areas of necrosis are often multifocal and rarely involving the whole gland. Necrosis develops early in the course of the disease and is usually established 96 hours after the onset of symptoms. The extent of pancreatic necrosis and the degree of peripancreatic inflammation have been used to determine outcome. A grading system combining the two CT prognostic indicators (the extent of necrosis and the grade of peripancreatic inflammation) gives the 'CT severity index'. [13]

A strong correlation has been established between the CT depiction of necrosis and the development of complications and death. [14] In patients with necrosis in the pancreatic head, the outcome is as severe as when the entire pancreas is affected. By contrast, for patients with necrosis in only the distal portion of the gland, the outcome is usually good, with few complications. The mechanism may be that necrosis in the pancreatic head causes obstruction of the pancreatic duct and produces a rise in pressure in the acinar cells leading to damage and leakage of activated destructive proteases.

Acute peripancreatic fluid collections occur in the first 4 weeks. These are simple fluid collections with poorly defined walls. Most remain sterile and will resolve spontaneously. If they fail to resolve, these collections can become more organised and develop a capsule; at this point, this collection is known as a pseudocyst. 50% will resolve, but the remainder can go on the develop complications such as infection, haemorrhage rupture and erosion into nearby vessels. They can also cause mass effect. [15] Repeat CT imaging is therefore indicated if the patient's clinical condition deteriorates.

Ultrasonography in acute pancreatitis is less useful since visualisation of the gland may be obscured by a 'gas-filled' bowel. However, there may be a role for this mode of imaging in demonstrating gallstones or duct dilatation, or in the subsequent management when ultrasound-guided fine-needle aspiration of the pancreas or surrounding tissue may help to establish the presence of infection.

Fluid Therapy

Appropriate intravenous fluid therapy is of paramount importance when treating patients with acute pancreatitis. Hypovolaemia arises from vomiting (± diarrhoea), poor oral intake, third spacing of fluid, oedema and diaphoresis. This results in hypotension, worsening tissue perfusion, exacerbating pancreatic tissue necrosis and precipitating dysfunction in other organ systems. A randomised trial conducted in patients with moderate to severe pancreatitis showed aggressive fluid resuscitation (20 mL/kg over 2 hours plus 3 mL/kg/h infusion) resulted in a higher incidence of fluid overload and did not improve outcomes. [16] Moderate hydration (1.5 mL/kg/h plus bolus 10 mL/kg if hypovolaemic) [16], [17] with an isotonic crystalloid solution was advised in all patients without contraindications. [17] Higher fluid administration rates (10–15 mL/kg/h) are associated with an increased need for mechanical ventilation (94% vs. 65%), intra-abdominal compartment syndrome, sepsis and mortality (30.6% vs. 10%) compared with a 5–10 mL/kg/h strategy. [18] Fluid status should be reassessed at frequent intervals in the first 24 hours. [16]

Plasma Exchange

Plasma exchange has been proposed to treat severe hypertriglyceridaemia (>11.3 mmol/L) acute pancreatitis. Mortality in patients is significantly higher if TG >11.3 mmol/L. [19] Plasmophoresis effectively reduces triglyceride levels, but a recent retrospective study has shown it does not reduce incidence and duration of organ failure. A large trial is needed before any clear recommendations can be made. [20]

Surgery in Severe Pancreatitis

During the 1980s, most patients with acute pancreatitis of even moderate severity underwent operative intervention; this was particularly true for those patients thought to have infected pancreatic necrosis. The results were poor, with mortality rates in excess of 50%. In the 1990s the concept of a conservative, non-surgical approach to severe ANP was developed. The aim now is often to postpone surgery for as long as possible and early referral to a specialist centre for supportive management is considered paramount.

Asymptomatic pseudocysts and pancreatic necrosis do not warrant surgical intervention, regardless of size and location, unless gastric outflow or bile duct patency is compromised. [17] In stable patients with infected necrosis, drainage should be delayed for a period of at least 4 weeks to allow the formation of a fibrous wall and liquefaction of the necrotic tissue. [21] Many patients improve such that intervention is unnecessary at this point.

Unstable patients with infected necrosis should receive a course of antibiotics to allow the inflammation to become organised prior to targeted, minimally invasive surgical intervention. [17, 22]

Many centres report that a conservative approach and avoiding open necrosectomy result in lower mortality. Open surgery is reserved for concomitant intra-abdominal complications, such as perforation, bleeding or ischaemia. [23]

If severe acute pancreatitis (AP) is an unsuspected ‘chance’ finding at laparotomy, a T-tube should be inserted into the common bile duct, particularly if it has been explored and the opportunity taken for placement of a feeding jejunostomy tube. Some surgeons oppose this approach, as opening a hollow viscus risks peritonitis.

For those patients with mild gallstone pancreatitis, the risk of recurrence is high (18% at 90 days), [17] early cholecystectomy is advocated to prevent recurrent and potentially more serious disease. In more severe biliary AP, cholecystectomy should be delayed until the inflammatory response and clinical picture have resolved. [24]

Pancreatic Abscesses

Pancreatic abscesses are circumscribed collections of pus containing little or no pancreatic necrosis, which arise as a later consequence of severe AP or pancreatic trauma. They commonly occur about 3–4 weeks after the onset of severe pancreatitis, and a CT scan most accurately makes the diagnosis. If the appropriate expertise is available, percutaneous catheter drainage may be very successful. Some series report effective drainage of intra-abdominal collections with a single treatment in 70% of patients, increasing to 82% with a second attempt, although proceeding to open surgical drainage is more frequently required in pancreatic abscess, especially if complicated by yeast infection.[25]

Endoscopic Retrograde Cholangiopancreatography

Endoscopic retrograde cholangiopancreatography (ERCP) represents an alternative approach, particularly for patients with severe biliary pancreatitis or those who are too frail for surgery. In mild gallstone pancreatitis, early ERCP decreases morbidity and mortality in patients with AP and biliary sepsis/obstruction, whereas in mild pancreatitis without cholangitis, the risks of intervention probably outweigh the benefits.[26]

This observation is confirmed by both a systematic review of the five ERCP trials[27] and by the recommendations of the 2013 International Association of Pancreatology on the management of severe AP in the critically ill.[22]

Treatment With Pharmacological Agents

Theories regarding the pathogenesis of AP have promoted the concept that autodigestion of the gland and peripancreatic tissue by activated pancreatic enzymes is a central component. This has led to the suggestion that the reduction of pancreatic exocrine secretion, thereby ‘resting the pancreas’, might improve outcome. The problem is that the secretory status of the pancreas in severe ANP is not known. Consequently, it is not clear whether inhibition of secretion actually occurs or whether this is beneficial. Therapies designed to inhibit pancreatic secretion, such as H_2-blockers, atropine, calcitonin, glucagon and fluorouracil, do not alter the course of the disease.

Other therapies are more controversial.

Somatostatin and Octreotide

Somatostatin and its long-acting analogue octreotide are potent inhibitors of pancreatic secretion. They also stimulate the activity of the reticuloendothelial system and play a regulatory role, mostly inhibitory, in the modulation of the immune response by blocking the release of tumour necrosis factor and interferon-g. Both analogues are cytoprotective with respect to the pancreas.[28]

These actions may be important in the modulation of the pathogenesis of ARDS and septic shock which may complicate severe ANP. However, both agents are powerful splanchnic vasoconstrictors. The development of pancreatic necrosis has been linked to blood flow and hypoperfusion of the gland has been shown to worsen the histological severity of experimental pancreatitis.[29]

Systematic evaluation suggests that there is insufficient evidence to support the use of octreotide or somatostatin in the treatment of patients with moderate to severe AP.[30], [31] Octreotide may have a role in prophylaxis prior to ERCP[32] but the ideal delivery method and dosage are not clear.

Protease Inhibitors

A further pathogenic mechanism involved in AP is autodigestion of the pancreas by the activation of proteases. More accurately, there is an imbalance between proteases and antiproteases. Aprotinin and gabexate mesilate are proteolytic enzyme inhibitors that act on serine proteases such as trypsin, phospholipase A_2, kallikrein, plasmin, thrombin and C1r and C1s esterases.

In a meta-analysis of 17 trials, protease inhibitors did not achieve a significant risk reduction in mortality, length of stay or need for surgery, even in severe disease.[33-35] The majority of published data is observational and to date, there are no placebo-controlled randomised studies evaluating protease inhibitors in ANP. There is insufficient evidence to recommend protease inhibitors in ANP and their use is not supported in the majority of published guidelines.[36], [37]

Anti-Inflammatory Therapy

Patients with ANP exhibit a generalised uncontrolled inflammatory response. Potentially there is a therapeutic window between the onset of symptoms and the development of organ failure during which anti-inflammatory therapy might be successful. Potential targets include tumour necrosis factor-α, interleukin (IL)-1β, IL-6, IL-8, IL-10, platelet-activating factor and intracellular adhesion molecules.[38] Although many have been studied in animals, there are limited human data.

There are currently no positive published trials of corticosteroid therapy in patients with ANP, and no evidence for use as either specific therapy other than as part of the treatment for associated septic shock.

Non-steroidal anti-inflammatory drugs (NSAIDs) have been evaluated in several studies and may provide a beneficial effect in reducing the incidence of post-ERCP pancreatitis.[39], [40] NSAIDS reduce ANP-related inflammation in preclinical studies and are effective in relieving pain in mild pancreatitis however adequately powered trials are lacking in severe disease.[39]

Recombinant IL-10, anti-TNF-α and platelet-activating factor (Lexipafant) have all been investigated in animal models, but there is insufficient human data, and the use of these agents is not recommended.[41]

Prophylactic Antibiotics

Bacterial infection of necrotic pancreatic tissue occurs in approximately 50% of patients with ANP, and infection is the major cause of morbidity and mortality. Early studies investigating the role of prophylactic antibiotics in AP showed no benefit, but most included patients with mild disease and employed agents (e.g. ampicillin) with inefficient penetration of pancreatic tissue. Subsequent studies have still not clarified their role, and prophylactic use remains widespread but controversial.

Carbapenems have exceptional penetration into pancreatic tissues and broad activity against most of the common pathogens encountered in this disease. In the 1990s there was hope that this new class of antibiotic would prove more useful, and some of the early trials did suggest a modest benefit with imipenem.[42] The incidence of septic complications was significantly reduced in the treated group (12.2% vs. 30.3%), although there was only a trend towards decreased mortality (7% vs. 12%). However, the most recent systematic review,[43] which included 7 trials (3864 patients), suggested antibiotic prophylaxis was not associated with a statistically significant reduction in mortality (odds ratio (OR) 0.69 [95% confidence interval (CI), 0.41–1.16]), in the incidence of infected pancreatic necrosis (OR 0.74 [95%

CI, 0.44–1.23]) or in the incidence of non-pancreatic infections (OR 0.64 [95% CI, 0.15–2.75]).[43]

Whilst antibiotic prophylaxis is not recommended, intravenous antibiotics should be given in cases of suspected infection of necrotising pancreatitis after aspiration or cultures have been performed.[17], [22]

Patients with mild pancreatitis do not benefit from antibiotics.

Prophylactic Antifungal Therapy

The incidence of fungal infection correlates with the extent of pancreatic necrosis, as well as the severity of the disease on admission. Antibiotic administration has been claimed to promote fungal infection; however, up to 25% of patients with ANP who do not receive antibiotics also develop fungal infection with an associated mortality rate of up to 84%.[44] Advocates of prophylactic antifungal therapy argue that it may delay the need for surgery, which is associated with a better outcome. Routine administration of antifungal agents is not recommended.[17]

Selective Decontamination of the Gut

Severe AP may be a clinical situation which supports the hypothesis that gut hypoperfusion promotes bacterial translocation, leading to infection of the inflamed pancreas and peripancreatic tissue.[45-47]

In a recent, large, multicentre trial investigating the use of selective digestive decontamination (SDD) in mechanically ventilated critically ill adults, the use of SDD was not associated with a significant reduction in in-hospital mortality, duration of mechanical ventilation or length of stay compared with standard care, however, there was a significant reduction in positive blood cultures and in cultures of resistant organisms. This study did not exclude patients with AP, but specific data for outcomes in this group is lacking.[48]

The only controlled trial of SDD in pancreatitis was performed in 102 patients[49] who were randomised to receive SDD: oral colistin, amphotericin and norfloxacin with the addition of a daily dose of the three drugs given as a rectal enema and systemic cefotaxime until Gram-negative bacteria were successfully eliminated from the oral cavity and rectum. There were 18 deaths (35%) in the control group, compared with 11 (22%)

in the SDD group ($P < .05$). This difference was caused by a fall in late mortality due to a significant reduction in the incidence of Gram-negative pancreatic infection. There was also a reduction in the mean number of laparotomies in the SDD patients. Since the SDD regimen used in this study incorporated intravenous cefotaxime, it could be argued that the improvement in outcome was not due to the colistin, amphotericin or norfloxacin components, but merely due to a systemic antibiotic effect.

Probiotics have been investigated in three prospective randomised controlled double-blinded studies. The studies were relatively small, and the results were contradictory. A non-significant reduction in mortality was seen in two of the studies.[50], [51] The third study observed an increase in gut ischaemia (5.9% vs. 0, $P = .004$) and mortality in the probiotic arm compared with the placebo (16% vs. 6%, RR, 2.53; 95% CI, 1.22–5.25).[52] Probiotics are not recommended.[53]

Nutritional Support in Acute Necrotising Pancreatitis

The provision of nutritional support for the patient with ANP is an essential component of supportive therapy, especially since many patients with pancreatitis are nutritionally depleted prior to their illness and face increased metabolic demands throughout the course of their disorder. Failure to reverse or prevent malnutrition, and a prolonged negative nitrogen balance, increases mortality rates.

Over half of all patients admitted to critical care requiring ventilation for AP have intra-abdominal hypertension (IAP > 12 mm Hg). IAP should be monitored in all patients as this will help guide management.[54]

Enteral Nutrition (EN)

EN in severe ANP is safe and feasible for all but the minority of patients. Enteral feeding maintains the gut mucosal barrier and helps prevent bacterial translocation and secondary infection of necrotic pancreatic tissue. Feeding should therefore commence early.

Enteral feeding can be oral, nasogastric or nasojejunal.[55] Nasogastric (NG) placement is easier than nasojejunal (NJ) and may therefore be preferential route; however, NG feeding is not tolerated by a number of patients. Intragastric delivery of nutrients may result in an increased volume of pancreatic protein and bicarbonate secretion, which, in combination with delayed gastric emptying, can precipitate vomiting and pain. It may therefore be preferable to place a nasojejunal tube with the tip distal to the third part of the duodenum, under radiological, endoscopic or magnetic guidance. The upper part of the duodenum contains cholecystokinin (CCK) secreting cells, stimulation of which causes gallbladder contraction and increased pancreatic exocrine secretion and may worsen the course of the disease. NJ feeding bypasses this area and conforms to the concept of ‘pancreatic rest’.

EN is associated with reduced infectious complications, organ failure and mortality compared with parenteral nutrition (PN). [56] A number of comparisons of EN with PN have been made in mild and severe AP, all suggesting that EN is well tolerated without adverse effects on the course of the disease. [57]

Total Parenteral Nutrition (TPN)

Some patients may not tolerate EN because of ileus and slow bowel transit time, nutritional support may still be required even after NJ insertion; in this situation, TPN or supplemental PN with normoglycaemic control is advocated. There is no evidence for upfront TPN if EN is feasible. Several retrospective and prospective evaluations of TPN in AP have failed to demonstrate conclusively an effect on survival, or on the incidence and severity of organ failure.

An international task force has recently made some recommendations, [58] which can be summarised as follows:

1. Patients with AP should be considered at moderate to high nutritional risk because of the catabolic nature of the disease.
2. Oral feeding with a low fat, soft oral diet should be offered as soon as clinically tolerated in patients with mild disease.
3. In patients who are unable to feed orally, enteral nutrition is preferred to parenteral and should be started early. Specific timing is controversial but 24–72 hours are considered safe time points.
4. If enteral nutrition is required it should be administered via a nasogastric tube, nasojejunal tube may be required in cases of

delayed gastric emptying, intrabdominal hypertension (IAP 15–19 mm Hg) or gastric outflow syndrome.

5. Parenteral nutrition should be administered in patients who do not tolerate EN or if abdominal compartment syndrome (IAP >20 mm Hg).
6. In all patients, whether fed enterally or parenterally, a protocol ensuring good glycaemic control is recommended. [58]

Conclusion

The main determinant of outcome in severe AP is the extent of pancreatic necrosis and the subsequent risk for the development of infected necrosis. A thorough assessment using appropriate scoring systems and the early use of dynamic contrast-enhanced CT will highlight those patients likely to benefit from early critical care. Despite numerous suggested specific therapies, there is still no incontrovertible evidence that anyone confers a significant mortality benefit. However, general supportive measures should include vigorous replacement of fluid losses to correct circulating volume, correction of electrolyte and glucose abnormalities, and respiratory, cardiovascular and renal support as necessary. Patients with sterile necrosis should receive a broad-spectrum antibiotic that adequately penetrates pancreatic tissue if they develop shock. Due attention should also be paid to nutritional support, for which EN is recommended prior to initiation of TPN.

Hepatic failure

Freya Glover, Rohit Saha and Brian J. Hogan

Liver Failure Definition

Liver failure is a generic term which describes a heterogenous group of disorders, with distinct aetiologies, management strategies and outcomes. Precise classification of the type of liver failure is important as it has significant implications for prognosis and management.

Patients with liver failure can be classified into two broad groups:

Acute Liver Failure (ALF) – an acute hepatic insult in a patient with no pre-existing chronic liver disease (CLD) which leads to both coagulopathy and encephalopathy.

Acute-on-chronic Liver Failure (ACLF) – the development of organ failures in patients with advanced chronic liver disease (ACLD) and acute decompensation (AD).

Acute Liver Failure

ALF is a rare condition with global variation in incidence and aetiology. In high-income countries, such as the United Kingdom, the annual incidence is 5–6 cases per million of the population.[1], [2] However, in low- or middle-income countries, the annual incidence has been reported to be over 60 cases per million people per year.[3]

ALF arises following massive liver parenchymal injury and hepatocyte loss which results in a multi-system disorder that is phenotypically similar to severe septic shock. ALF manifests as coagulopathy and encephalopathy, which occurs within days or weeks of the liver injury. Prompt recognition, resuscitation and referral to a specialist centre are essential to achieve good outcomes.[4]

Classification

There are three distinct clinical phenotypes of ALF: hyperacute, acute and subacute. These were characterised by O'Grady et al. using the time from the onset of liver injury to the development of encephalopathy, called the 'jaundice to encephalopathy time'[5] (Table 54.1).

Table 54.1

O'Grady Classification of acute liver failure

DEFINITION	TIME (DAYS)	COMMONEST AETIOLOGIES
Hyperacute	<7 days	Paracetamol overdose, hepatitis A and B
Acute	8–28 days	Hepatitis A, B, E, idiosyncratic drug reactions
Subacute	29 days–8 weeks	Idiosyncratic drug reaction, seronegative hepatitis

Hyperacute liver failure progresses rapidly – jaundice to encephalopathy (J-E) time ≤7 days. It is associated with profound coagulopathy, high-grade encephalopathy, severe organ dysfunction and a high incidence of intracranial hypertension but confers higher rates of spontaneous survival. Onset of encephalopathy can precede clinical jaundice.

ALF has an intermediate course. Common aetiologies include viral hepatitis and idiosyncratic drug reactions.

Subacute liver failure is associated with a later onset of encephalopathy, and the worst outcomes in the absence of liver transplantation. Aetiology is frequently either seronegative (history suggests a viral or immune-mediated aetiology, but all serological tests are negative) or drug related. Jaundice is significant but transaminitis is often less pronounced than in acute and hyperacute presentations. Patients can present with both ascites and other early features of portal hypertension so may be clinically difficult to distinguish from those with ACLD.

Prognosis

Assessment of prognosis is important in the management of ALF and is closely related to both the clinical phenotype and the cause of liver injury. Survival has improved significantly over recent decades. Transplant-free survival rates in high-income countries, such as the United Kingdom or the United States, are 69%–75% for paracetamol and 39%–59% for non–paracetamol aetiologies when assessed at either hospital discharge or at 21 days respectively.[6], [7] It is essential to identify patients unlikely to survive without liver transplantation so that assessment and urgent listing can be expedited. One-year survival post-liver transplantation is excellent at 90%–91% and this remains a lifesaving intervention for those with a poor prognosis.[8], [9] A particular challenge for current practice is to identify borderline patients who may have historically been offered liver transplantation, but who with modern critical care support may survive without surgery.[10]

ALF prognostic scores are summarised in Box 54.1 . Of these, the modified King's College Criteria (KCC) is most frequently used for prognostication. Model for end-stage liver disease (MELD) may be useful for prognostication in non–paracetamol ALF.[11] The Sequential Organ Failure Assessment (SOFA) score and the ALF Study Group index have also been used. It is essential that such scoring systems are rigorously applied and in the context of paracetamol are only utilised at least 24 hours post-ingestion and following appropriate volume resuscitation.

Box 54.1

Prognostic criteria for acute liver failure

Modified Kings College criteria

Paracetamol related:

Any of:

- Arterial pH <7.25 (despite 24 hours of fluid resuscitation)
- All three of:
    - an international normalised ratio (INR) of greater than 6.5
    - serum creatinine of greater than 300 µmol/L
    - encephalopathy (of grade III or IV).
- Serum Lactate >4.0 mmol/L (despite 24 hours of fluid resuscitation)

Non–paracetamol-related:
Favourable aetiologies (ecstasy/acute viral hepatitis) with encephalopathy:

- INR >6.5 (PT >100 sec) or
- Three of: INR >3.5 (PT >50 sec), age >40 or <10 years, bilirubin >300 µmol/L and J-E >7 days.

Unfavourable aetiologies (idiosyncratic drug-induced, indeterminate)

- INR >6.5, or
- if hepatic encephalopathy is absent then INR >2 and any two from the following: age >40 or <10 years; INR >3.5
- if hepatic encephalopathy is present then jaundice to encephalopathy time >7 days; serum bilirubin >300 µmol/L.

French criteria (Clichy criteria)

The criteria are the presence of ≥ grade 3 hepatic encephalopathy, and
Age <30 years with factor V level <20%, or
Age >30 with factor V levels <30%

INR , International normalised ratio.

Importantly, in subacute liver failure, a reducing liver volume on imaging is associated with a poor prognosis – particularly if the volume falls below one litre.[12]

Aetiology

Identifying the aetiology of ALF (Box 54.2) is important for prognostication and target therapies. There is wide geographical variation in the aetiology of ALF: in the United Kingdom and United States paracetamol (acetaminophen) toxicity is most common, whereas globally it is viral hepatitis (Table 54.2).[3, 7, 13-17] Higher rates of seronegative hepatitis reported in low-income countries may represent a paucity of available diagnostic testing.

Box 54.2

Aetiology of acute liver failure

Viral hepatitis

- Hepatitis A, B, D, E
- Herpes simplex, cytomegalovirus, chickenpox – usually limited to immunocompromised hosts

Drug-induced liver injury

- Paracetamol
- Anti-microbials
- Anti-epileptic drugs
- Anti-tuberculous drugs
- Recreational drugs (MDMA, cocaine)
- Others (Propylthiouracil, disulfiram, Non-steroidal anti-inflammatory drugs)
- Herbal Remedies

Seronegative hepatitis

Toxins

Carbon tetrachloride, phosphorous, Amanita phalloides, alcohol

Vascular events

Ischaemia, veno-occlusive disease, Budd–Chiari syndrome (hepatic vein thrombosis)

Pregnancy

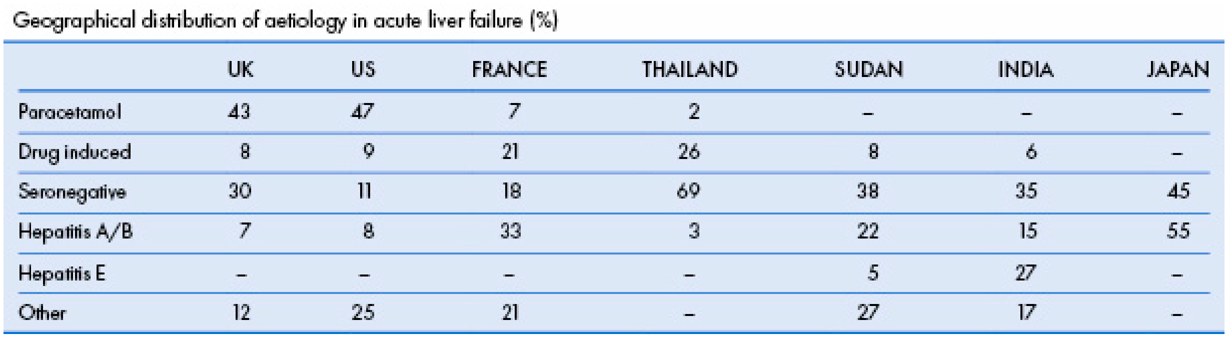
Acute fatty liver of pregnancy, HELLP syndrome (haemolysis (microangiopathic haemolytic anaemia), elevated liver enzymes and low platelets), liver rupture

Other

Wilson disease, autoimmune, malignancy, HLH (haemophagocytic lymphohistiocytosis), trauma, hyperthermic liver injury

---

Table 54.2



Geographical distribution of aetiology in acute liver failure (%)

	UK	US	FRANCE	THAILAND	SUDAN	INDIA	JAPAN
Paracetamol	43	47	7	2	–	–	–
Drug induced	8	9	21	26	8	6	–
Seronegative	30	11	18	69	38	35	45
Hepatitis A/B	7	8	33	3	22	15	55
Hepatitis E	–	–	–	–	5	27	–
Other	12	25	21	–	27	17	–

Diagnosis

A standardised investigative pathway ensures clinical consistency. Laboratory tests that may be useful in establishing a diagnosis are listed in Table 54.3 . It is paramount that diagnostic tests proceed in tandem with the assessment and management of organ failure.

Table 54.3

CT , Computed tomography; *HELLP* , haemolysis (microangiopathic haemolytic anaemia), elevated liver enzymes and low platelets; *HbsAg* , hepatitis B surface antigen; *HIV* , human immunodeficiency virus; HV, high velocity; *LDH* , lactate dehydrogenase.

An extensive history (including travel, past medical history and family history) and review of the results of blood tests from preceding weeks are essential to make a diagnosis. Any new drug ingestion (prescribed, recreational or over-the-counter) should be considered a potential culprit and discontinued if possible.

Liver imaging is essential and axial computed tomography (CT) provides additional information about abdominal anatomy, lymphadenopathy and an assessment of liver parenchyma and perfusion. In ALF the liver and abdomen usually appear normal.[18] Serial imaging in ALF may demonstrate a collapsing liver (Fig. 54.1). Nodularity of the liver should not be assumed to represent ACLD as the features of subacute liver failure, with focal areas of collapse and regeneration, may be difficult to distinguish from cirrhosis. In addition, early features of portal hypertension can be seen in subacute liver failure. Doppler ultrasound may be useful in determining patency of the hepatic artery, hepatic veins and portal vein.

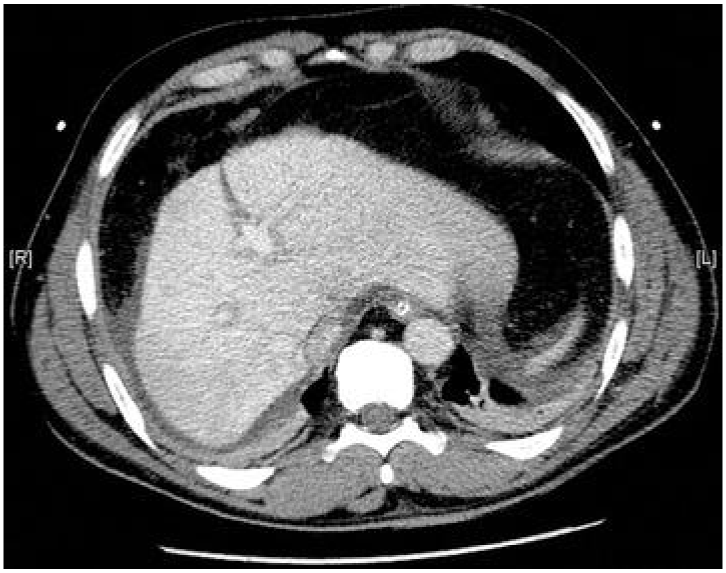


FIG. 54.1 A collapsed liver in the case of a 42-year-old male with acute liver failure.

Liver biopsy is a useful diagnostic tool, particularly in non–paracetamol aetiologies. It should ideally be performed via the transjugular route to reduce bleeding complications.[19,20] In ALF, non-specific confluent necrosis and panacinar collapse is the commonest histological finding. Its severity has been used to assess outcome: >50% necrosis is associated with poor prognosis. Histological features suggestive of specific diagnoses, such as Wilson disease and autoimmune features may be evident. Histology may be particularly useful if tumour infiltration is suspected, and a tissue diagnosis is required prior to consideration of systemic chemotherapy.

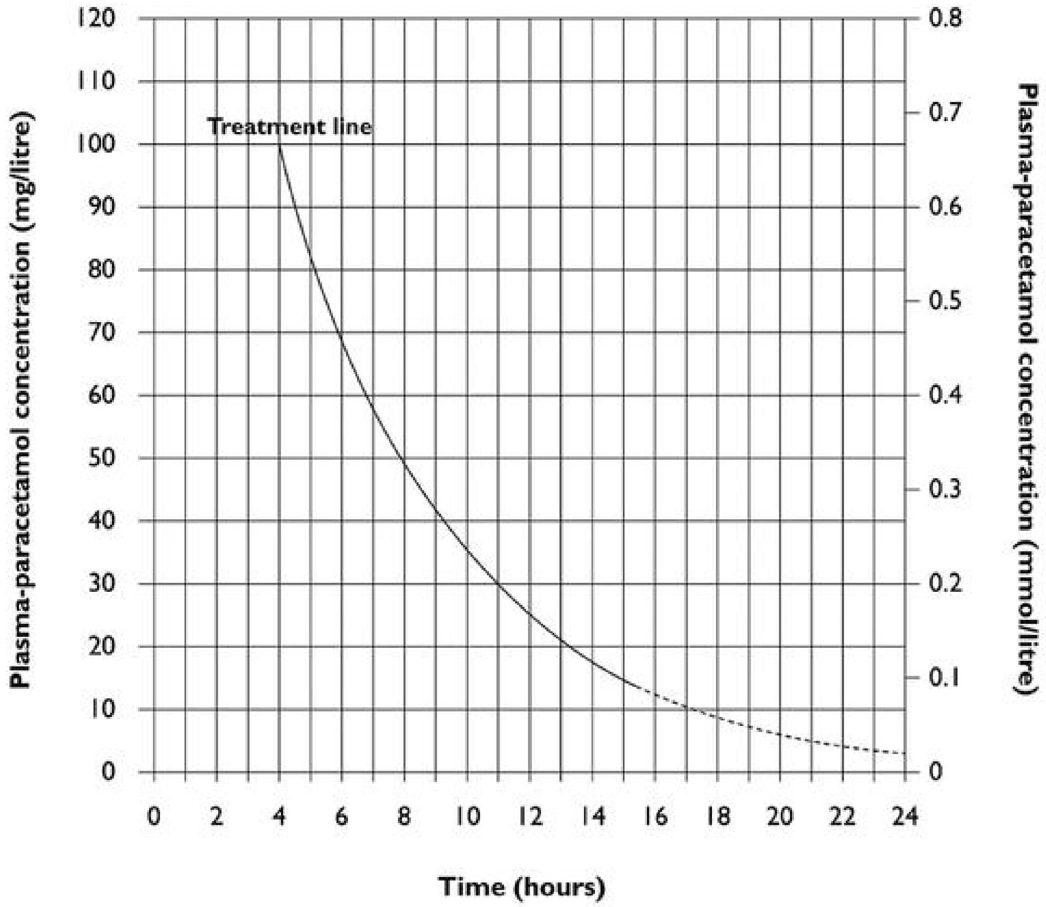
Echocardiography should be performed to exclude low cardiac output states as a cause of hypoxic hepatitis, and where transplantation is being considered.

Paracetamol Toxicity

Paracetamol, taken intentionally or inadvertently, remains one of the most common forms of acute hepatotoxicity. The incidence of mortality from paracetamol intoxication had been steadily rising in the United Kingdom from the 1970s until intervention from the UK Medicines Control Agency in 1998 when legislation to limit its availability was introduced, reversing this trend.[21] Combined analgesics confer a risk of inadvertent overdose when they are abused for their narcotic content.

Cytochrome P450 enzymes convert approximately 10%–15% of paracetamol to N-acetyl p-benzoquinone imine (NAPQI), a metabolite that is normally detoxified by conjugation with hepatic glutathione. Hepatocellular glutathione becomes rapidly depleted in overdose, and NAPQI persists, causing damage to cell membranes leading to hepatocyte death unless N-acetylcysteine (NAC) or methionine is administrated in a timely fashion. [22] NAC is hydrolysed intra-cellularly to cystine which replenishes glutathione, the latter binds NAPQI and treatment within eight hours of ingestion ensures a non-fatal outcome in almost all patients. In higher doses of paracetamol ingestion, NAPQI results in direct mitochondrial toxicity and severe metabolic acidaemia with hyperlactataemia. [23]

Classically, early signs of nausea, vomiting and abdominal pain after overdose are followed by features of liver failure 48–72 hours after ingestion. In addition to components of the King’s College criteria, unintentional overdose, the absence of a reliable overdose history, increasing age and thrombocytopaenia were independent predictors of death based on a multivariate analysis of 663 UK cases. [24] The modified Prescott nomogram (Fig. 54.2) is used in the United Kingdom and Europe to determine the risk of paracetamol toxicity. It can be applied only to a single acute overdose (ingested total overdose within a one-hour time period) presenting within 16–24 hours. It should be noted that negative paracetamol levels 16–24 hours after ingestion do not exclude the potential for hepatotoxicity.



Patients whose plasma-paracetamol concentrations are on or above the **treatment line** should be treated with acetylcysteine by intravenous infusion.

The prognostic accuracy after 15 hours is uncertain, but a plasma-paracetamol concentration on or above the treatment line should be regarded as carrying a serious risk of liver damage.

Graph reproduced courtesy of Medicines and Healthcare products Regulatory Agency

The graph displays a treatment line which represents plasma paracetamol concentration over time in a person who has ingested paracetamol. The horizontal axis represents time in hours, which ranges from 0 to 24. The vertical axis on the left shows plasma paracetamol concentration in milligrams per litre, ranging from 0 to 120. The vertical axis on the right displays the equivalent concentration in millimoles per litre, ranging from 0 to 0.8. The curve representing the treatment line starts at one hundred milligrams per litre at four hours and steadily declines over time, reaching approximately ten milligrams per litre by 17 hours, and continues to decrease beyond that point. A note at the bottom states that patients whose plasma paracetamol concentrations are on or above the treatment line should be treated with acetylcysteine by intravenous infusion. It also mentions that prognostic accuracy after 15 hours is uncertain, but values on or above the treatment line suggest a serious risk of liver damage.

FIG. 54.2 The modified Prescott nomogram.

A staggered overdose is said to have occurred where there have been multiple ingestions over time. If the history of overdose is unclear, or when there is a potential staggered overdose or other clinical concern then NAC should be commenced as it can be lifesaving. Even late administration of NAC (up to 36 hours after ingestion) may improve outcome. The risk factors listed in Table 54.4 [25] confer a predisposition to paracetamol-induced hepatotoxicity.

Table 54.4

Risk factors for paracetamol hepatotoxicity

DECREASED HEPATIC GLUTATHIONE STORES	INDUCTION OF CYTOCHROME P450
Anorexia nervosa	Phenytoin
Bulimia	Carbamazepine
HIV	Rifampicin
Cystic fibrosis	Phenobarbital
Malnourishment	Long-term ethanol ingestion

HIV , Human immunodeficiency virus.

From Greene SL, Dargan PI, Jones AL. Acute poisoning: understanding 90% of cases in a nutshell. *Postgrad Med J* . 2005;81(954):204–216 (published by BMJ group).

NAC has traditionally been administered as a ‘3-bag’ regimen: (150 mg/kg in 5% dextrose over 15–60 minutes, followed by 50 mg/kg in 5% dextrose over four hours, and then by 100 mg/kg in 5% dextrose over 16 hours). Consensus guidelines for the management of paracetamol overdose now recommend a ‘2-bag’ regimen which slows the initial loading dose. This appears to be equally effective and associated with a significantly lower risk of anaphylactoid reactions when compared to the ‘3-bag’ regimen. [26] Since 2021, the UK Royal College of Emergency Medicine has recommended the abbreviated Scottish & Newcastle Acetylcysteine protocol (SNAP) – 100 mg/kg NAC in 5% glucose or 0.9% sodium chloride over two hours, followed by 200 mg/kg NAC in 5% glucose or 0.9% sodium chloride over 10 hours. A similar recommendation is made in guidelines from Australia and New Zealand: 100 mg/kg NAC in 5% glucose or 0.9% sodium chloride over four hours, followed by 200 mg/kg NAC in 5% glucose or 0.9% sodium chloride over 16 hours. [27]

Plasma paracetamol and alanine transaminase (ALT) levels should be rechecked at, or just before the end of the treatment regimen to decide if further administration of NAC is indicated.

Ongoing administration at doses of 150 mg/kg over 24 hours may be indicated in severe liver injury. Patients with features of moderate or severe overdose should be managed in a critical care environment; the importance of early appropriate fluid resuscitation should not be underestimated. Contact should be made with a tertiary centre, and cases discussed with decision to transfer made in a timely fashion.

Acute Viral Hepatitis

Acute viral hepatitis accounts for 40%–70% of patients with ALF worldwide.

Acute hepatitis A virus (HAV) infection rarely leads to ALF (0.35% of infections) but continues to account for up to 10% of cases; morbidity increasing with age. It is hoped that prevalence will decrease with improving hygiene standards generally and increased uptake of vaccination.

Acute hepatitis B virus (HBV) causes 25%–75% of viral hepatitis-induced ALF, although only 4% of patients with acute HBV will develop ALF. Liver injury is immunologically mediated with active destruction of infected hepatocytes. Diagnosis is by the presence of the immunoglobulin (Ig)M antibody to hepatitis B core antigen. Hepatitis B surface antigen (HBsAg) is frequently negative at the time of presentation. Hepatitis B DNA should also be assayed. ALF may also be seen with hepatitis D as either a co-infection or supra-infection.

Re-activation of hepatitis B is increasingly recognised as a cause of ALF and should always be considered in a patient who has received immunosuppression for example with steroids or chemotherapy. Patients initiating immunosuppressing treatment should be screened for hepatitis B core antibody (HBcAb) and prophylaxis with antiviral agents commenced if this is positive.

Hepatitis C virus (HCV) infection is commonly associated with ACLD but not with ALF. It is detected by the presence of antibodies to HCV in serum.

Hepatitis E virus (HEV), like HAV, is transmitted via the faecal–oral route. It is particularly prevalent in the Indian subcontinent and Asia and is responsible for sporadic cases of ALF in the Western world. HEV can be diagnosed by the detection of IgM antibodies to HEV in serum or via HEV RNA levels. Mortality can be as high as 25% in pregnant women.

Other viruses, such as herpes simplex -1 and -2, varicella-zoster virus, cytomegalovirus, Epstein–Barr virus and measles virus may all rarely cause ALF, particularly in immunocompromised patients. Diagnosis is by serological and polymerase chain reaction testing. Rift Valley fever, dengue fever, yellow fever, Lassa fever and haemorrhagic fevers should be considered in those who are at risk.

Seronegative Hepatitis

A cause for ALF can be established in approximately 60%–80% of patients. Seronegative hepatitis is diagnosed in patients in whom there are no identifiable causes or obvious candidate drugs. Such patients may present with a prodromal illness and with acute or subacute manifestations of the disease. Prognosis is poorer than those with an identifiable virus. In patients with poor prognostic criteria, the chances of survival without liver transplantation are small. A subgroup may represent an acute autoimmune form of ALF, although many will not have any positive immune markers such as elevated IgG or positive smooth-muscle or liver-kidney antibodies. The pattern of markers shows an increased incidence of autoantibody positivity in seronegative cases and viral cases with elevated IgM in viral causes. [28]

Drug-Induced Liver Injury

Drug-induced hepatitis is responsible for approximately 15%–25% of cases of ALF. In some patients, there appears to be a true hypersensitivity reaction, and symptoms develop after a sensitisation period of 1–5 weeks, recur promptly with re-administration of the drug and may be accompanied by fever, rash and eosinophilia. In others, the clinical pattern is less acute and liver failure can manifest up to six months after exposure. Some herbal remedies are implicated as putative hepatotoxins, but their role is made more difficult to assess by the variable nature of the constituent parts.

Recreational drugs and liver failure

MDMA (methylenedioxymethamphetamine) may cause ALF, and the severity of liver injury is known to be dose related. Proposed mechanisms of injury include immune-mediated mechanisms and/or heatstroke. Cocaine use may result in ischaemic hepatitis. Yellow phosphorus, carbon tetrachloride, chloroform, trichloroethylene and xylene (glue sniffing) are rare causes of ALF.

Amanita Phalloides

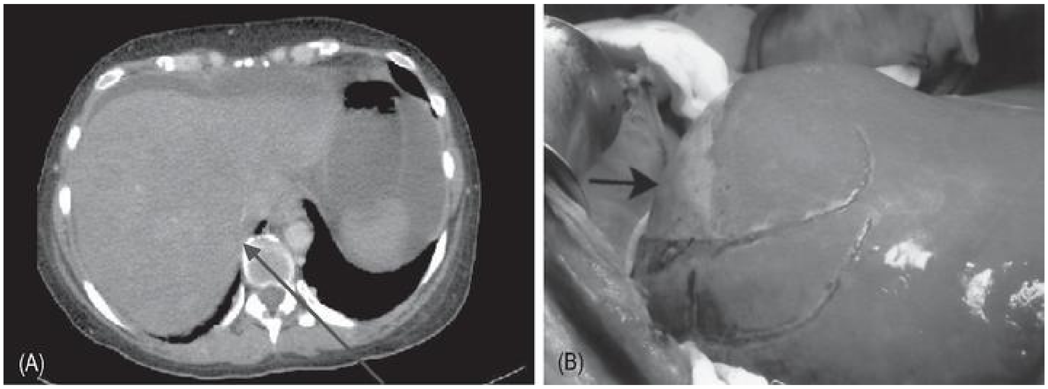
Mushroom poisoning can be seen even when only very small amounts have been ingested (e.g. Amanita phalloides). The initial presentation is often with diarrhoea. Patients subsequently develop signs of hepatic necrosis at 2–3 days after ingestion. Liver injury is caused by amatoxins. Forced diuresis may be helpful as large amounts of toxin are excreted in urine, but inadvertent dehydration may result in renal failure. Thioctic acid, silibinin (silybin) and penicillin have been advocated as therapy but have not been subjected to controlled trials.

Wilson Disease

Acute presentations of Wilson disease are frequently seen in patients with pre-existing cirrhosis. The classical clinical features are hyperbilirubinaemia with a low alkaline phosphatase and direct antiglobulin test (DAT) negative haemolysis. Caeruloplasmin (which would usually be low in Wilson disease) may be normal or raised with acute inflammation. Kayser–Fleischer rings may be present in up to 50% of cases.

Acute Budd–Chiari Syndrome (Hepatic Venous Obstruction)

Hepatic venous obstruction (Budd–Chiari syndrome) may cause ALF. There are symptoms and signs of liver necrosis, often with capsular pain from congestion and ascites. Thrombus may be associated with anatomical anomalies of the inferior vena cava but is normally related to thrombosis of the hepatic veins, often with an underlying procoagulant condition (Fig. 54.3).



The two-part figure is labelled A and B. Part A is a computed tomography scan that shows an axial cross-section of the upper abdomen. The liver is located on the right side, and a hypodense area is visible in the central region of the liver. A thin arrow points toward this area. The diaphragm and abdominal wall are visible surrounding the liver. Part B is an intraoperative surgical view of an exposed liver. A thick arrow points to a linear laceration on the liver surface, which extends horizontally across the anterior aspect of the liver. The liver surface shows multiple parallel linear disruptions consistent with trauma.

FIG. 54.3 (A) Acute Budd–Chiari syndrome: The intrahepatic inferior vena cava *(arrow)* is grossly attenuated. (B) Budd–Chiari liver: The arrow shows liver necrosis; ischaemic/infarcted liver.

Hyperthermic liver injury

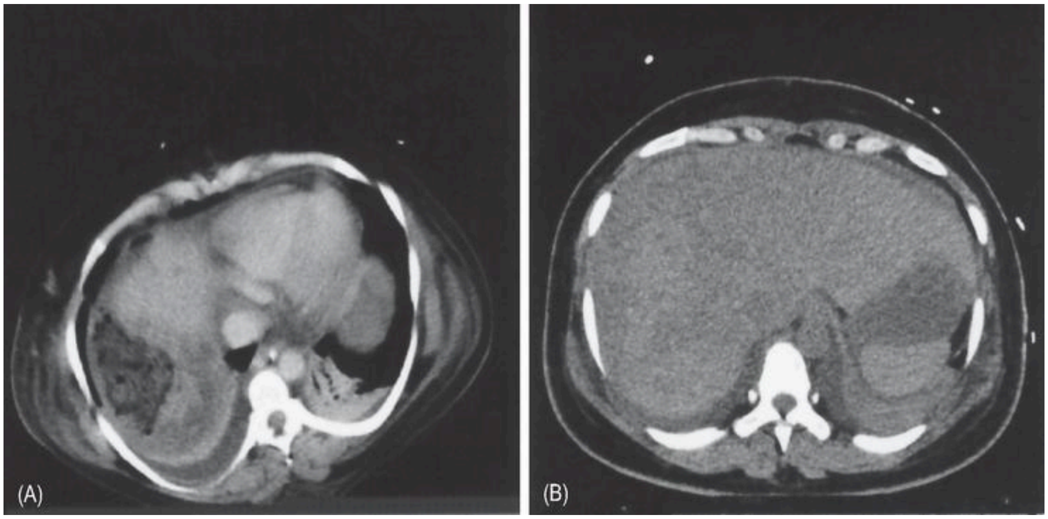
Thermal liver injury is seen with recreational drug use, such as MDMA or with occupational or recreational exposure to elevated body temperature. The liver injury is usually seen in the context of multi-organ failure and rhabdomyolysis.

Ischaemic Hepatitis

Ischaemic hepatitis is commonly seen in critical care, where it is present in 2.5% of admissions and is the cause of 40% of cases where the ALT is >10 × the upper limit of normal. [29] Increasing age and prior liver congestion from right heart failure are particular risk factors. A documented episode of hypotension or hypoperfusion is only seen in 50% of cases. Treatment should be focused on restoring perfusion. Ischaemia may also result from vascular occlusion; imaging should seek to ensure patency of portal and hepatic vessels.

Pregnancy-Related

Pregnancy-related liver failure syndromes include haemolysis [microangiopathic haemolytic anaemia], elevated liver enzymes and low platelets (HELLP), acute fatty liver of pregnancy and liver rupture, often in association with pre-eclampsia. The prognosis of pregnancy-related ALF is usually good, although some develop severe liver injury with small-vessel disease. Ruptured livers may require laparotomy and packing and occasionally liver transplantation is required (Fig. 54.4).



The two computed tomography scans are labelled A and B. Part A is an axial view from a computed tomography scan of the upper abdomen. The liver is located on the right side and displays irregular contours with mixed areas of hypoattenuation and hyperattenuation. Part B is another axial view from a computed tomography scan of the upper abdomen at a similar level. The liver in this part appears with a smooth contour and homogeneous density across its parenchyma. There are no irregular lesions or abnormal densities noted in the liver in Part B.

FIG. 54.4 Liver computed tomography in pregnancy-related liver disease demonstrating abnormal perfusion (A and B) with rupture, packing (A) and associated areas of infarction. Major bleeding into the liver.

Malignancy

Malignancy may also present with ALF, albeit rarely. The clinical pattern normally is that of elevated cholestatic liver enzymes. Elevated transaminases and hepatomegaly may also be present. In addition to hepatic infiltration with solid organ tumours, this pattern of disease may be seen in those with hepatic involvement in lymphoma, often with elevated lactate dehydrogenase, or other haematological malignancy.

Clinical Features and General Management

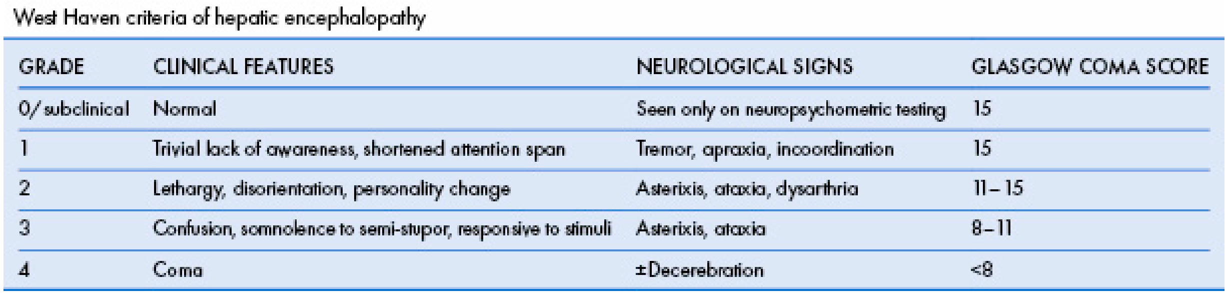
Jaundice

The O’Grady classification uses the time from jaundice to encephalopathy to describe ALF as either hyperacute, acute or subacute (Table 54.1). In hyperacute liver failure (paracetamol toxicity, Amanita poisoning and acute viral hepatitis), encephalopathy may precede the onset of clinical jaundice.

Hepatic Encephalopathy

Hepatic encephalopathy (HE) is clinically classified using the West Haven criteria. Initially described by Parson-Smith (Table 54.5), it is based on functional impairment, changes in consciousness, cognitive function and behaviour. The presence of encephalopathy is essential for a diagnosis of ALF.

Table 54.5



West Haven criteria of hepatic encephalopathy

GRADE	CLINICAL FEATURES	NEUROLOGICAL SIGNS	GLASGOW COMA SCORE
0/subclinical	Normal	Seen only on neuropsychometric testing	15
1	Trivial lack of awareness, shortened attention span	Tremor, apraxia, incoordination	15
2	Lethargy, disorientation, personality change	Asterixis, ataxia, dysarthria	11–15
3	Confusion, somnolence to semi-stupor, responsive to stimuli	Asterixis, ataxia	8–11
4	Coma	±Decerebration	<8

Intracranial Hypertension

HE is frequently complicated by cerebral oedema and intracranial hypertension with diminished cerebral perfusion and risk of transtentorial herniation. Onset is rapid and allows little time for adaptive mechanisms (in contrast to patients with ACLD where there is time for adaptation and control of cellular osmolarity). This has implications for the transfer of patients with ALF between hospitals: intubation and ventilation with adequate sedation and implementation of neuroprotective strategies (see below) should be considered prior to transfer in any patient with progressive HE.

Patients with high-grade encephalopathy (coma) are at greatest risk of developing cerebral oedema. Elevated arterial ammonia levels, a higher MELD score, younger age and requirement for vasopressor and renal replacement therapy (RRT) are independent risk factors for HE. Arterial ammonia levels greater than 200 µmol/L are associated with cerebral herniation.[30,31]

Ammonia is produced by bacteria in the bowel and is taken up by cerebral astrocytes for deamination to glutamine. Water is drawn into the intracellular compartment down its osmotic gradient. There are also induced changes in neurotransmitter synthesis and release, mitochondrial function and neuronal oxidative stress. The net result is astrocyte swelling and cerebral oedema.[32,33]

The association between the development of HE and markers of inflammation is well demonstrated, and an increase in inflammatory mediators such as tumour necrosis factor (TNF) has been reported.[34,35] It is not yet clear if treatments that aim to reduce inflammation more broadly, such as corticosteroids, or specific targets in the inflammatory cascade will be of benefit.

Blood–brain barrier injury, increased cerebral blood flow and hyperaemia accompanying astrocyte swelling can potentiate cerebral oedema independently of astrocyte glutamine concentration. Thus, cerebral oedema may be vasogenic with inflammatory disruption of the blood–brain barrier or cytotoxic with osmotic dysregulation.

Cerebral blood flow is coupled to cerebral metabolic rate, arterial oxygen and carbon dioxide tensions and acid–base status. The ‘toxic liver hypothesis’ describes the situation whereby there is a massive release of pro-inflammatory cytokines in association with the profound systemic inflammatory response and accumulation of toxic metabolites that accompany ALF. Altered cerebral blood flow and loss of autoregulation occur in the face of this inflammatory milieu.

The Munro–Kellie hypothesis states that the intracranial cavity is essentially an incompressible box and that an increase in the volume of one of the intracranial components (blood, brain and cerebrospinal fluid) must be accompanied by a decrease in the volume of another. CT studies have demonstrated that effacement and ventricular attenuation are frequent radiological findings in ALF.

Diencephalic transtentorial herniation causes posterior cerebral artery insufficiency with temporal, thalamic and occipital infarction; obstructive hydrocephalus; and brainstem ischaemia, compression and death.

The normal range for intracranial pressure (ICP) is 7–15 mm Hg (0.93–2 kPa) in the supine adult. Many definitions of intracranial hypertension have been volunteered, but a pressure of greater than 20 mm Hg (2.66 kPa) for a period of 20 minutes should be considered worthy of treatment. The US ALF Study Group recommends osmotic therapy for patients with an ICP greater than 25 mm Hg (3.33 kPa). [36]

Clinical management of the cerebral complications of ALF has developed pragmatically and by extrapolation from the neurosurgical literature. However, with modern critical care management, prevention of intracranial hypertension is possible in most patients and should be the focus of care.

The use of invasive ICP monitoring is now uncommon. Advocates would point out that clonus, brisk reflexes and hypertonicity can be detected clinically, but pupillary changes, systemic hypertension and reflex bradycardia are not apparent until intracranial hypertension is established, and that radiographic changes are non-specific. Sceptics would point out the lack of randomised controlled trial (RCT) evidence showing outcome benefits with ICP monitoring in ALF and the risk of intracranial haemorrhage with ICP monitoring. The US ALF group found bleeding complications in up to 10% of patients, although many institutions use parenchymal monitors, which may be more accurate but are associated with a higher bleeding risk. Non-invasive methods, including transcranial Doppler ultrasonography, tympanometry and optic nerve ultrasound have been used and may add to the clinical assessment. [37], [38]

Standard practice in the authors' institution is that patients whose conscious level deteriorates to below grade 2 HE are electively intubated, sedated and ventilated with the head end elevated at 30 degrees.

Unnecessary stimulation is avoided. A combination of opiate (e.g. fentanyl) and propofol sedation is commonly used. The decision to move to ICP monitoring is highly individual and is supported by a hyperacute presentation, younger age and higher arterial ammonia levels (>150 mmol/L). Decision making is frequently supported by reverse jugular venous oximetry and Doppler estimation of middle cerebral arterial flow.

A cerebral perfusion pressure of greater than 50 mm Hg (6.66 kPa) has been suggested as optimal. Patients with ALF often do not autoregulate cerebral blood flow to systemic arterial pressure. Consequently, increases in blood pressure may be associated with increased ICP, particularly if they are at a critical point on their pressure–volume curve. Sustained cerebral perfusion pressures of less than 40 mm Hg (5.33 kPa) have been associated with very poor outcomes in some studies, whereas others report good outcomes despite periods of cerebral hypoperfusion.[39]

Invasive cardiovascular monitoring is mandatory – we advocate flow monitoring to guide fluid resuscitation. Norepinephrine (noradrenaline) and vasopressin are commonly used pressor agents. The use of bolus dose terlipressin was associated with a rise in ICP in one study.[40]

In most patients, maintenance of $PaCO_2$ between 4.5 and 5.0 kPa is considered ideal. Cerebral blood flow is intimately coupled to arterial carbon dioxide tension; minute ventilation must therefore be carefully controlled. Acute respiratory distress syndrome (ARDS) is relatively common and lung-protective ventilatory strategies should be used.

Hyponatraemia and hyperammonaemia have been shown to be detrimental, whereas an RCT showed benefits in patients whose serum Na was maintained between 145 and 155 mmol/L.[41] The use of hypertonic saline was associated with a significant reduction in ICP, although the same study was not powered to detect a difference in outcome.

First-line treatment for a sustained rise in ICP is hypertonic saline (e.g. 2 mL/kg of 3% sodium chloride). Serum osmolarity must be monitored and maintained at less than 320 mOsm to avoid damage to the blood–brain barrier and worsening of vasogenic oedema. Mannitol is now rarely used in this setting.

Hypothermia has been shown to reduce cerebral blood flow, ICP and cerebral ammonia uptake.[42,43] Prophylactic hypothermia (34°C) was not shown to offer any survival benefit over normothermia (36°C), but any fever should be avoided. [44]

Other treatment options that have been shown to be potentially beneficial are thiopental and intravenous indomethacin (0.5 mg/kg). [45]

Sepsis

Sepsis is common in ALF and both culture-positive infection and culture-negative inflammatory responses are seen. Patients are functionally immunosuppressed with impaired cell-mediated immunity and phagocytosis, reduced complement levels, and monocyte dysfunction. [46] , [47] Clinicians should pay scrupulous attention to hand washing and line care to decrease the risk of nosocomial infection. We would also recommend regular culture screens and a low threshold for initiation of antimicrobials in patients with any clinical suggestion of sepsis. Prophylactic intravenous antifungals should be considered, especially in those listed for liver transplantation. The choice of antimicrobial agent should be driven by local resistance patterns and antimicrobial therapy should be regularly reviewed in the light of culture results.

Coagulopathy

Coagulopathy is the hallmark of ALF, with prolongation predominantly of the prothrombin time and to lesser degrees the activated partial thromboplastin ratio (APTR). In a small percentage of patients who may be vitamin K deficient, the coagulopathy will improve, at least partially, with vitamin K and 10 mg is normally administered intravenously. Thrombocytopenia is common and frequently consumptive in nature. Bleeding is rare, although it may be seen in those with severe prolongation of APTR, low fibrinogen and severe thrombocytopenia. [48] Point-of-care thromboelastography (TEG) usually shows a rebalanced normal or hypercoagulable state, rather than hypocoagulable features. [49] Repletion of coagulation factors is necessary for clinical bleeding and prophylactically before major invasive procedures (such as ICP bolt insertion). Coagulation support is normally not given routinely for other procedures, such as invasive line insertions so that the international normalised ratio (INR) can be monitored regarding prognosis.

Cardiovascular Considerations

Patients with ALF develop hyperdynamic circulation with peripheral vasodilation and central volume depletion. Hypotension is common and may initially respond to volume repletion. Assessment of volume responsiveness in the clinical setting may be difficult and pressure measurements are a poor indicator of volume status. Hypotension that does not respond to volume will usually require some form of invasive haemodynamic monitoring and the institution of vasopressor agents. Assessment of fluid tolerance requires bedside clinical and echocardiographic assessment and invasive monitoring.

The requirement for pressor agents should raise the possibility of critical illness-associated adrenal dysfunction. Patients with ALF have been demonstrated to have impaired responses to adrenocorticotropic hormone.[50], [51] We would recommend a low threshold for initiation of shock dose steroids but prolonged administration beyond clinical improvement should be avoided.

Respiratory Considerations

Ventilatory support is frequently required in patients with ALF, usually because of a decreased conscious level rather than hypoxia, at least in the initial stages of the disease.

Common respiratory complications include pleural effusions, atelectasis and intrapulmonary shunts. ARDS may occur and can be precipitated by extrapulmonary sepsis or inflammation.

Ventilatory strategies are influenced by both the respiratory and the multi-organ involvement that is characteristic of ALF. Thus, patients with deep levels of coma and who are at risk of cerebral oedema will require close attention to CO_2 levels and tailored sedation regimens. Hypercapnia may have to be tolerated in patients progressing to ARDS. This requires balancing against the cerebral needs of these patients as hypercarbia and increased cerebral blood flow will tend to increase ICP. Pleural effusions may require drainage if they are impeding ventilation. Weaning may be facilitated by undertaking a tracheostomy during the recovery period of ALF.

Renal Considerations

Renal failure is common, with an incidence as high as 50%. Incidence is even higher – up to 75% – with paracetamol-induced liver failure, where the drug may exert a direct toxic effect on the renal tubule.[39] The aetiology of acute renal dysfunction is frequently multifactorial, with hepatorenal syndrome being a rare occurrence. Acute tubular necrosis (ATN) and pre-renal renal failure are common. As such, volume therapy and maintenance of intra-vascular blood volume are essential in the management of such patients, as is the avoidance of nephrotoxins. Intra-abdominal hypertension is frequent and may contribute to renal dysfunction; measurement of intra-abdominal pressure may be a valuable component of monitoring.

Established renal failure requires the institution of RRT using continuous methods and bicarbonate (rather than lactate) buffer solutions. In patients with ALF, early consideration should be given to RRT to control fluid balance and acid–base disturbances and to avoid rapid changes in osmolarity. It may limit or control elevations of arterial ammonia and prevent the development of cerebral complications.

The choice of anticoagulation for RRT needs to balance the risk of bleeding versus the risk of filter clotting. For patients at high risk of bleeding, options include targeting conservative activated partial thromboplastin time (APTT) or factor Xa levels when using heparin, running filters without anticoagulation, or the use of agents such as citrate or prostaglandins (e.g. epoprostenol). Although citrate clearance is reduced in patients with liver failure,[52] its use in this patient group has been shown to be feasible.[53,54] When using regional citrate anticoagulation in patients with liver failure, clinicians should be wary of citrate accumulation and have a low threshold for dose adjustment or switching to an alternative anticoagulation option. In patients with thrombocytopenia, consideration should be given to the diagnosis of heparin-induced thrombocytopenia and, if confirmed, heparin should be withdrawn, and circuits primed with an alternative agent (e.g. danaparoid).

Metabolism and Feeding

Enteral nutrition should commence as soon as feasible if there are no contraindications. In patients with large volume aspirates (>400 mL/4 h), a prokinetic agent should be commenced: erythromycin (250 mg intravenously 6-hourly) appears to be more effective than metoclopramide. Placement of a post-pyloric feeding tube should be considered in refractory cases, although this may need to be delayed in patients with or at risk of cerebral oedema. The optimal constitution of the enteral feed used has not been investigated, but ALF patients have increased calorific requirements. [55] Patients with ALF demonstrate both peripheral and hepatological insulin resistance. [56]

Metabolic acidosis is a relatively frequent occurrence that may relate to lactic acidosis, hyperchloraemic acidosis or renal failure. Hyperlactataemia may be secondary to volume depletion and hence will resolve with appropriate fluid loading or may reflect the inability of the liver to metabolise the lactate produced. A failure of blood lactate to return to <2 mmol/L following volume loading is associated with a poor prognosis. [57] Metabolic acidosis may be a secondary effect of other drugs ingested as part of an episode of self-harm. A reduction in serum phosphate levels in patients with paracetamol-induced ALF is thought to be associated with liver regeneration and a good prognosis. [58] Pancreatitis is a common complication of ALF and should be actively considered, with a low threshold for additional imaging. Liver transplantation in the setting of acute pancreatitis can be associated with a poor prognosis. [59]

Therapeutic Plasma Exchange

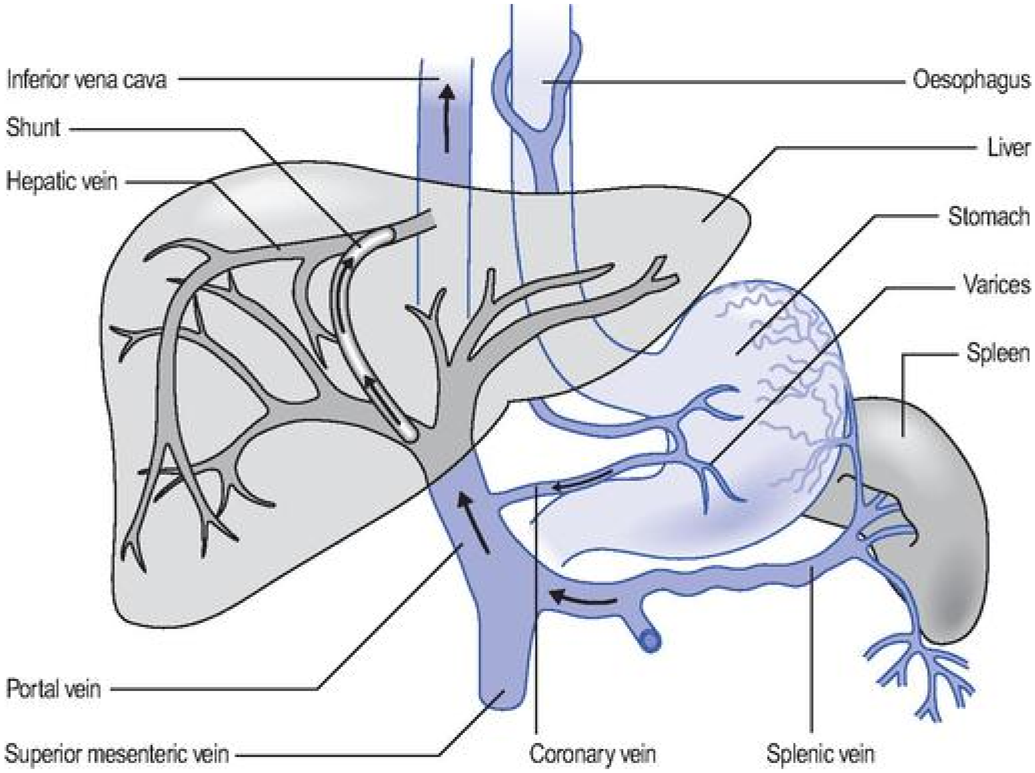
Therapeutic plasma exchange (TPE) has been assessed in two RCTs for the treatment of ALF. A European study of 183 patients showed improved survival with TPE using high-volume exchanges of 8–12 L with fresh frozen plasma (FFP) in patients who were not suitable for liver transplantation. [60] An Indian study, also using 1–2 plasma volumes showed a reduction in 21-day mortality. [61] The authors offer TPE to patients with poor prognostic criteria who are not suitable for liver transplantation, or as a bridge to liver transplantation in patients with increasing vasopressor requirements or refractory hyperammonaemia.

Specific Treatments

Management of ALF is largely supportive, providing an optimal environment for either regeneration or stability until a suitable liver becomes available. Once patients develop poor prognostic criteria the chances of effective liver regeneration and thus of spontaneous recovery are low; prognosis is poor without liver transplantation.

- The role of extracorporeal liver support systems remains a hope for the future, but at present no system has been shown to have a definitive survival benefit in a controlled trial.
- NAC is administered for paracetamol-induced ALF, as mentioned above. Its role in non–paracetamol-induced ALF remains undefined, although a US study suggests that it may be of benefit in patients with ALF and grade 1–2 HE (presumably because liver transplantation is required to impact the outcome in patients with higher HE grades). [62]
- Chelating agents are not of benefit in patients with established ALF secondary to Wilson disease but have an important role in chronic disease. The withdrawal of such treatments, or indeed non-compliance – especially in teenagers – may precipitate ALF.
- Antiviral therapy is used to prevent the re-activation of hepatitis B in patients exposed to chemotherapy and steroids.
- Thrombolytic therapies may be of benefit in patients with early acute Budd–Chiari syndrome, although increasingly the treatment option would be to perform a transhepatic portosystemic shunt (TIPS), decompressing the liver with a stent passed either through the hepatic vein (if the clot is soft enough) or via the inferior vena cava and through to the portal vein (Fig. 54.5). Such procedures should be undertaken in units with access to liver transplantation due to the risk of precipitating ALF.
- Chemotherapy may be offered to those with lymphoma involving the liver and, in these instances, histology is paramount, either of the liver or from another diagnostic site.
- Steroid therapy is beneficial in acute autoimmune hepatitis but its role in autoimmune ALF has been less clear, due to the increased

risk of infection. If steroids are commenced it is vital to assess response and not delay decisions on the need for liver transplantation. [63]



Inferior vena cava
Shunt
Hepatic vein
Oesophagus
Liver
Stomach
Varices
Spleen
Portal vein
Superior mesenteric vein
Coronary vein
Splenic vein

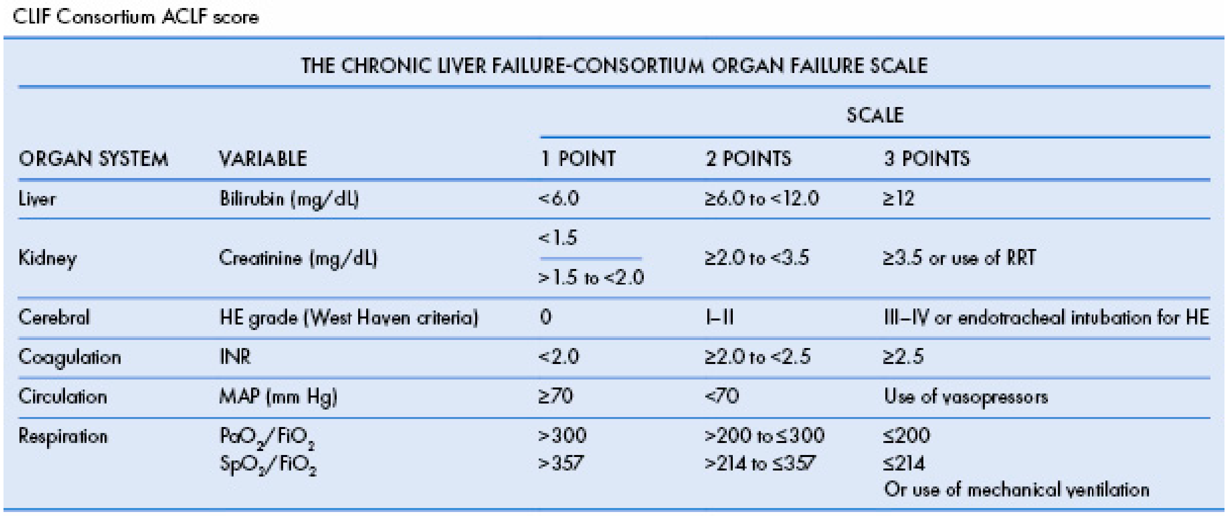
The labelled anatomical diagram presents the hepatic and portal venous circulation with emphasis on vascular connections among abdominal organs. The liver is centrally located and partially transparent, revealing the internal branching structure of the hepatic veins. The inferior vena cava runs vertically behind the liver. A shunt connects the portal vein to the hepatic venous system, diverting blood from the portal vein directly into the systemic circulation. The portal vein enters the liver from below, formed by the confluence of the superior mesenteric vein and the splenic vein. The splenic vein extends from the spleen on the far right, coursing medially to join the portal vein. The coronary vein drains into the portal vein near its junction. The stomach lies anterior to the portal system, connected by varices, which are dilated venous channels extending toward the oesophagus. These varices are shown branching from the stomach wall and leading upward. The hepatic veins are shown draining blood from the liver into the inferior vena cava.

FIG. 54.5 Transjugular intrahepatic portal systemic shunt.

Advanced Chronic Liver Disease and Acute-On-Chronic Liver Failure

CLD is diagnosed when liver dysfunction has been present for more than 6 months. Complications of ACLD present far more commonly in the critical care unit than ALF. Acute deterioration (AD) refers specifically to the development of ascites, encephalopathy, gastrointestinal haemorrhage and/or intercurrent bacterial infections. Organ failures (liver, kidney, brain, coagulation, respiration and circulation) are defined by the CLIF-C ACLF score (CLIF being an abbreviation for chronic liver failure) (Table 54.6).[64] ACLF is a syndrome characterised by AD, organ failures and high short-term mortality. Acute deteriorations in hepatic and extrahepatic organ function in the previously stable patient with cirrhosis are frequently precipitated by infection and bleeding (often variceal) but may also reflect a trajectory of decline in liver function in a patient with end-stage disease.

Table 54.6



CLIF Consortium ACLF score

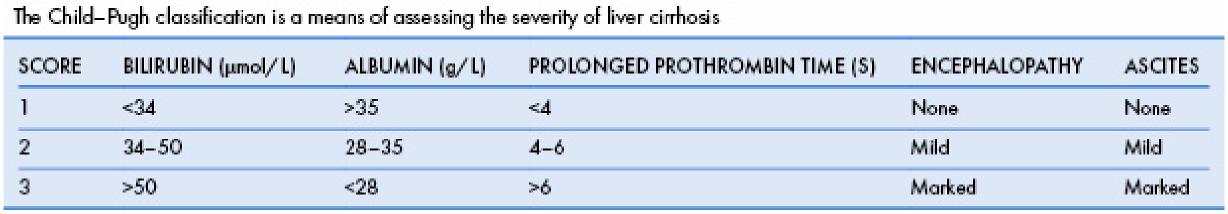
THE CHRONIC LIVER FAILURE-CONSORTIUM ORGAN FAILURE SCALE

		SCALE		
ORGAN SYSTEM	VARIABLE	1 POINT	2 POINTS	3 POINTS
Liver	Bilirubin (mg/dL)	<6.0	≥6.0 to <12.0	≥12
Kidney	Creatinine (mg/dL)	<1.5 >1.5 to <2.0	≥2.0 to <3.5	≥3.5 or use of RRT
Cerebral	HE grade (West Haven criteria)	0	I–II	III–IV or endotracheal intubation for HE
Coagulation	INR	<2.0	≥2.0 to <2.5	≥2.5
Circulation	MAP (mm Hg)	≥70	<70	Use of vasopressors
Respiration	PaO_2/FiO_2 SpO_2/FiO_2	>300 >357	>200 to ≤300 >214 to ≤357	≤200 ≤214 Or use of mechanical ventilation

CLIF , Chronic liver failure; *FiO* $_2$, fraction of inspired oxygen; *INR* , international normalised ratio; *MAP* , mean arterial pressure; *PaO* $_2$, partial pressure of arterial oxygen; *RRT* , renal replacement therapy. Reproduced from Zaccherini G, Weiss E, Moreau R. Acute-on-chronic liver failure: definitions, pathophysiology and principles of treatment. JHEP Rep. 2021;3(1). https://doi.org/10.1016/j.jhepr.2020.100176 .

Cirrhosis is a histological diagnosis made when there is a significant architectural distortion of the liver parenchyma caused by increasing fibrosis and the development of nodules, it was traditionally diagnosed using liver biopsy. Modern cross-sectional imaging and non-invasive testing such as transient elastography means that many patients do not require a biopsy to diagnose advanced fibrosis or cirrhosis. For this reason, the term ACLD is increasingly preferred to represent those with more advanced fibrosis who are at risk of AD. [65] The term ACLD is also supported by patient representatives as it is not associated with the stigmatising term ‘cirrhosis’. [66] The Child–Pugh score (Table 54.7) is often used to classify the severity of ACLD.

Table 54.7



The Child–Pugh classification is a means of assessing the severity of liver cirrhosis

SCORE	BILIRUBIN (μmol/L)	ALBUMIN (g/L)	PROLONGED PROTHROMBIN TIME (S)	ENCEPHALOPATHY	ASCITES
1	<34	>35	<4	None	None
2	34–50	28–35	4–6	Mild	Mild
3	>50	<28	>6	Marked	Marked

If there is primary biliary cirrhosis or sclerosing cholangitis then bilirubin is classified as <68 = 1; 68–170 = 2; >170 = 3.

The individual scores are summed and then grouped as:

- <7 = A
- 7–9 = B
- >9 = C

Aetiology of Chronic Liver Disease

There are myriad causes of CLD. Those most frequently encountered are listed in Box 54.3 . Acute-on-chronic presentations are relatively common and patients with previously unrecognised cirrhosis may decompensate following unrelated medical interventions. Where possible, planned interventions in patients with documented cirrhosis should be undertaken in specialist centres with appropriate peri-procedural support.

Box 54.3

Common aetiologies of chronic liver disease

- Metabolic-dysfunction Associated Steatotic Liver Disease (MASLD)
- Chronic infection with hepatitis B and C viruses
- Alcohol
- Primary biliary cirrhosis

- Autoimmune chronic active hepatitis
- Primary sclerosing cholangitis
- Budd–Chiari syndrome
- Veno-occlusive disease
- α_1-antitrypsin deficiency
- Wilson disease

Physiological Changes in Patients with ACLD

It is important to appreciate the multi-system changes that occur in response to ACLD when patients are stable, to understand their impact on physiology during decompensation. The liver vasculature normally has high compliance and low resistance and can accommodate large volumes of blood flow via the hepatic portal circulation without significant increases in portal pressure. As liver fibrosis progresses, there is intrahepatic vascular endothelial dysfunction. This is a result of activated hepatic stellate cell-induced fibrosis, sinusoidal remodelling, regenerative nodule formation and angiogenesis.[67] Mural inflammation and the formation of regenerative nodules further increase intrahepatic portal resistance by compressing central veins. Endothelial dysfunction results in reduced nitric oxide production which causes intrahepatic vasoconstriction and increased resistance to portal blood flow. Vasoconstriction is worsened by increased catecholamine and thromboxane A2 production. As increased intrahepatic vascular resistance develops there is compensatory reciprocal splanchnic arterial vasodilation, driven by local extrahepatic production of vasodilatory mediators such as nitric oxide and endogenous cannabinoids. This results in reduced systemic vascular resistance and effective systemic hypovolaemia as blood pools in the splanchnic bed. As a result, in patients with decompensated ACLD mean arterial blood pressure is relatively low, despite an elevated cardiac output state manifested by a resting tachycardia.[68, 69]

Increased intrahepatic resistance and portal hypertension alter portal flow, opening up collateral channels (varices), causing ascites to develop and driving portal congestion of the GI tract, resulting in bacterial translocation. [70] The new delicate physiological balance reached in ACLD is sensitive to minor insults: patients are at risk of decompensation in response to infection, gastrointestinal bleeding or medications and in severe cases, develop ACLF.

Cardiovascular

Cardiovascular complications of ACLD and portal hypertension occur due to the hyperdynamic circulatory syndrome described above, in which reduced systemic vascular resistance and tachycardia result in an increased cardiac output. [71] As liver disease progresses, these changes are insufficient to compensate for the effective systemic intra-vascular hypovolaemia, and compensatory neurohormonal pathways such as the renin-aldosterone-angiotensin system (RAAS) and sympathetic nervous systems are triggered. [72] This increases renal retention of sodium and water, worsening accumulation of ascites and the development of hyponatraemia. There is also increased venous return to the heart through portosystemic shunts; these processes help to maintain a high cardiac output state.

'Cirrhotic cardiomyopathy' is estimated to be present in up to 50% of patients with ACLD being assessed for liver transplantation. It is important to recognise its presence as it can alter responses to physiological stressors such as infection, and during procedures such as liver transplantation or TIPS. [73] The definition of cirrhotic cardiomyopathy was revised in 2019 according to criteria from the cirrhotic cardiomyopathy consortium and is defined as a left ventricular ejection fraction of less than or equal to 50% and/or absolute global longitudinal strain <18% in patients with ACLD. [74] It is characterised by abnormal contractile response to stress, altered diastolic relaxation or with electrophysiological abnormalities such as prolonged QTc duration, in the absence of known cardiac disease.

Respiratory

The most common pulmonary vascular complications in patients with ACLD are portopulmonary hypertension and hepatopulmonary syndrome. Portopulmonary hypertension occurs in 5%–8.5% of patients being considered for liver transplantation. [75] In portopulmonary hypertension the development of pulmonary hypertension is driven by portal hypertension, changes in splanchnic blood flow and vasoactive mediators.[76] Portopulmonary hypertension is associated with a preserved or elevated cardiac output in addition to increased pulmonary vascular resistance.[77] It presents with exertional dyspnoea, fatigue, chest pain, syncope and signs of right heart failure.[78, 79] Diagnosis relies on the exclusion of other causes of dyspnoea (e.g. large volume ascites and fluid retention). Transthoracic echo and then right heart catheterisation are required to confirm the diagnosis of portopulmonary hypertension: pulmonary artery systolic pressure 20 mm Hg or greater and elevated pulmonary vascular resistance.[80] Severe portopulmonary hypertension is a contraindication to liver transplantation, and so management with dual modality vasodilatory agents is initiated to improve symptoms, as a bridge to liver transplantation, the only curative treatment.[78, 79]

Hepatopulmonary syndrome (HPS) occurs in patients with ACLD, with or without portal hypertension. It occurs due to intrapulmonary vasodilatation (IPVD), which causes ventilation-perfusion mismatch and limits oxygen diffusion through the dilated pulmonary vessels.[81] IPVDs act as physiologic shunts, with improvement in oxygenation if supplemental oxygen is given. HPS commonly presents with dyspnoea at rest or on exertion, platypnoea and orthodeoxia.[82] These can be assessed by measuring oxygen saturations/PaO_2 in supine and upright positions.[83] HPS is diagnosed by identifying IPVDs on contrast TTE.[84] The only treatment for HPS is liver transplantation; patients with HPS and PaO_2 <60 mm Hg on room air should be evaluated for liver transplantation.[85] Mortality approaches 80% without liver transplantation.

Hepatic hydrothorax (HH) occurs in patients with ACLD and is defined as fluid in the pleural space in the absence of underlying cardiac, renal or pulmonary disease. It is associated with morbidity and mortality, with a median survival of 8–12 months from diagnosis.[86] It is usually associated with large-volume ascites. HH occurs due to the direct passage of ascites into the pleural cavity through small defects in the tendinous structure of the diaphragm. This is driven by the inherent negative intrathoracic pressure gradient in combination with raised intra-abdominal pressure due to the accumulation of ascitic fluid. HH is right-sided in most cases (~85%), postulated to be due to the more muscular structure of the left hemidiaphragm. [87] Pleural aspiration is essential in confirming the diagnosis. Pleural fluid is typically a transudate by Light's criteria. Treatment with diuretics is key and TIPS can relieve symptoms or be a bridge to liver transplantation. HH is an indication for liver transplantation; eligible patients should be assessed for suitability. In patients with respiratory failure secondary to HH or refractory HH, thoracocentesis can be performed to fully drain the pleural cavity, although fluid tends to re-accumulate rapidly. Recurrent thoracocentesis and chest drain insertion are associated with high short-term mortality, and are associated with greater complication rates (pneumothorax and haemothorax) than pleural procedures performed in non-HH patients. [88] Indwelling pleural catheters can be inserted for symptomatic relief in patients, and may be more suitable in patients for palliative management as it is associated with higher complication rates than thoracocentesis or chest drain insertion. [89]

Renal

Acute Kidney Injury (AKI)

Up to 50% of patients with ACLD admitted to hospital have an AKI, and AKI affects 58% of ACLD patients admitted to ICU. [90-92] As in patients without CLD, AKI can be categorised as pre-renal, renal and post-renal. The most common causes of AKI in ACLD are hypoperfusion due to hypovolaemia – approximately 50%, ATN – 30%, and hepato-renal syndrome (HRS-AKI) – 15%–20%. Post-renal causes account for less than 1%. [93]

The diagnostic definition of AKI has been updated to follow the Kidney Disease Improving Global Outcomes (KDIGO) criteria of a rise in creatinine of 0.3 mg/dL in 48h, or 50% in seven days. In patients with ACLD, creatinine overestimates the glomerular filtration rate due to reduced creatinine production from protein-calorie malnutrition and muscle wasting. Serum creatinine can also lag by several hours or days behind renal function in patients with AKI and fluid overload. It is therefore important to interpret creatinine in the context of ACLD and changes in urine output should be considered an earlier and more sensitive marker of

AKI.[91] Initial management of AKI should include withdrawal of diuretics and nephrotoxic drugs (non-selective beta blockers, NSAIDs, vasodilators and ACE inhibitors), and evaluation of the patient's fluid status.

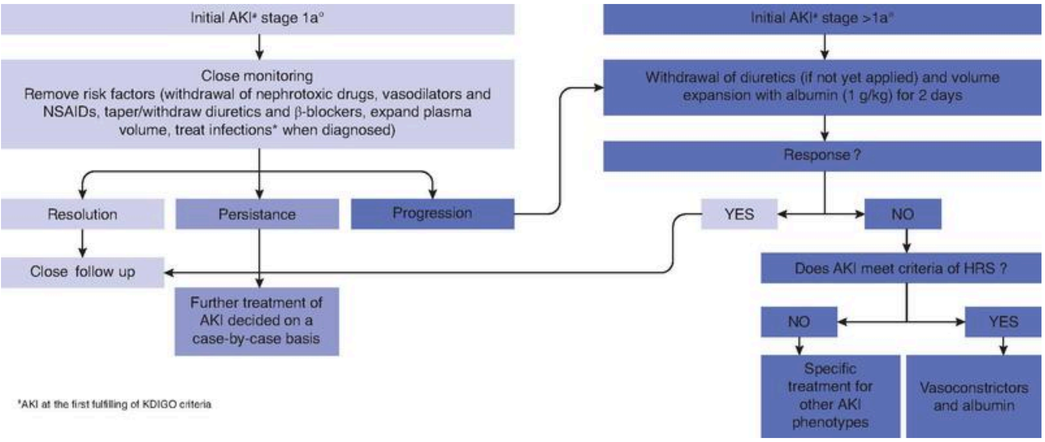
In patients with decompensated ACLD and ascites, if there is no response to volume resuscitation, a diagnosis of HRS-AKI may be suspected. HRS-AKI is a diagnosis of exclusion made after pre-renal AKI and ATN have been ruled out. International Ascites Club (IAC) Criteria for the diagnosis of HRS-AKI are shown in Box 54.4.[94] There are no specific biomarkers for the diagnosis of HRS-AKI, although urinary neutrophil gelatinase-associated lipocalin and functional excretion of sodium may be useful in discriminating between pre-renal azotemia, ATN and HRS-AKI.[95], [96] Given the potential lag in serum creatinine compared to clinical status, we would advocate a proactive approach in patients with AKI: once HRS-AKI is suspected in an appropriately volume-resuscitated patient, treatment with vasoconstrictor agents in combination with albumin should not be delayed.[97], [98] Splanchnic vasoconstriction shunts blood into the systemic circulation, increasing mean arterial pressure and effective circulating volume, reducing activation of the neurohormonal mechanisms contributing to renal arterial vasoconstriction, and so restoring renal perfusion. This approach to the classification and management of AKI in patients with ACLD is summarised in Fig. 54.6.[99]

Box 54.4

Diagnostic criteria for hepatorenal syndrome

- Cirrhosis with ascites
- Creatinine >1.5 mg/dL
- No improvement in serum creatinine (>1.5) after 2 days of diuretic withdrawal and volume expansion with albumin (1 g/kg/day up to 100 g/day)
- Absence of shock
- No nephrotoxins

- Absence of parenchymal kidney disease (proteinuria >500 mg/day, microhaematuria >50 red blood cells per high-power field) and/or abnormal renal ultrasound



Initial AKI* stage 1a°
Close monitoring
Remove risk factors (withdrawal of nephrotoxic drugs, vasodilators and NSAIDs, taper/withdraw diuretics and β-blockers, expand plasma volume, treat infections* when diagnosed)
Resolution
Persistance
Progression
Close follow up
Further treatment of AKI decided on a case-by-case basis
*AKI at the first fulfilling of KDIGO criteria
Initial AKI* stage >1a°
Withdrawal of diuretics (if not yet applied) and volume expansion with albumin (1 g/kg) for 2 days
Response ?
YES
NO
Does AKI meet criteria of HRS ?
NO
YES
Specific treatment for other AKI phenotypes
Vasoconstrictors and albumin

The clinical flowchart outlines the diagnostic and treatment approach for acute kidney injury. It begins with stage 1 a A K I and close monitoring, which includes removal of risk factors, such as withdrawal of nephrotoxic drugs, N S A I D, diuretics, beta blockers, and treatment of infections. Outcomes include resolution, persistence, or progression. For A K I beyond stage 1 a, diuretics are withdrawn, and volume expansion with albumin 1 gram per kilogram for 2 days is initiated. If there is a response, the patient returns to prior monitoring. If not, the chart assesses whether the A K I meets hepatorenal syndrome criteria. H R S is treated with vasoconstrictors and albumin; otherwise, phenotype-specific A K I treatment is given. Further treatment of A K I is decided on a case-by-case basis under persistence.

FIG. 54.6 Treatment algorithm for the management of AKI in ACLD. (From European Association for the Study of the Liver. EASL Clinical Practice Guidelines for the management of patients with decompensated cirrhosis. *J Hepatol* . 2018;69(2):406–460.)

The vasoconstrictor agent of choice is often terlipressin, which has now been approved in the United States and is superior to a combination of midodrine and octreotide.[100,101] Terlipressin and noradrenaline have similar efficacy, but terlipressin can be administered peripherally in a ward setting. It is important to monitor for pulmonary complications: terlipressin is associated with pulmonary oedema. These measures are successful in reversing AKI in 40%–70% of cases.[102,103] Other considerations include paracentesis in combination with albumin replacement in patients with tense ascites if it is felt that raised intra-abdominal pressure is contributing to impaired renal venous drainage, although there is insufficient evidence to support this practice routinely.[104] The definitive treatment for HRS-AKI is liver transplantation in appropriately selected patients. Other therapies under investigation is the use of TIPS for HRS-AKI; a meta-analysis of nine small studies suggested a significant improvement in renal function after TIPS, although there is currently insufficient evidence to recommend TIPS for HRS-AKI.[105]

Mortality associated with RRT is similar between patients with ACLD who have AKI; independent of the cause of AKI.[106,107] Our usual practice is to initiate RRT early to optimise fluid balance and correct metabolic disturbances.[105]

CKD

As the incidence of metabolic-associated steatotic liver disease (previously termed non-alcoholic fatty liver disease) increases, we expect that chronic kidney disease (CKD) due to hypertension, diabetes mellitus or a combination of the two will be encountered more frequently. HRS-CKD (previously known as HRS-2) is a more indolent process than HRS-AKI and is associated with refractory ascites. It is diagnosed when the estimated glomerular filtration rate is <60 mL/min for three months or more.[108] As with HRS-AKI, the definitive treatment for HRS-CKD is liver transplantation. In cases with prolonged renal dysfunction, simultaneous liver and kidney transplant can be considered, as renal recovery after liver transplantation is less likely in this case.[109,110]

Central Nervous System

Hepatic encephalopathy (HE)

HE is an important consequence of ACLD and is associated with an increase in mortality independent of other organ failures.[111] It is the strongest risk factor for hospitalisation and trauma.[112], [113] Overt HE occurs in 30%–45% of patients with ACLD, although up to 60% will have minimal HE.[114], [115] Ammonia is believed to be the main pathophysiologic driver in HE, although emerging areas of interest are the gut microbiome and aromatic amino acids.[116] Ammonia is produced by bacterial catabolism of urea in the colon. In the absence of CLD, it is metabolised in the liver and cleared by the kidneys and muscles.[117] Ammonia metabolism is impaired in ACLD and ammonia is shunted to the systemic circulation due to portal hypertension.[118] Ammonia crosses the blood–brain barrier, where it is metabolised by astrocytes to glutamine, leading to astrocyte swelling and the formation of reactive oxygen species. Following this, HE ensues. Clinical signs of HE with asterixis develop as ammonia suppresses inhibitory postsynaptic neurons.[119]

Clinical signs of HE include inattention, reduction in psychomotor response times and visuospatial ability progressing through to personality changes and disturbance of the sleep-wake cycle to acute confusion with agitation, somnolence and coma. The onset of overt HE is marked by disorientation or asterixis. Assessment should seek to exclude alternative causes of altered mental state, for example, alcohol withdrawal or electrolyte disturbance. Serum ammonia is not required to diagnose HE and does not affect its staging or prognosis in those with ACLD; its use in isolation leads to mis/overdiagnosis of HE.[120] Conversely, normal ammonia in a patient with ACLD and altered mental state should prompt a search for an alternative cause.[121] Head CT may be useful, although it is frequently negative in the absence of focal neurological signs and symptoms.[122] Electroencephalogram (EEG) may be useful for the exclusion of alternative causes of altered mental state, such as non-convulsive status epilepticus.[122] Electroencephalogram (EEG) can show changes associated with encephalopathy, but these changes are not specific to HE. If HE is suspected, the investigation should focus on determining its precipitant. Common precipitants include infection, constipation, hyponatraemia, gastrointestinal bleeding and medications (particularly diuretics). HE can also emerge after TIPS placement.[123]

First line treatment of HE is with non-absorbable disaccharides such as lactulose. These are metabolised by colonic microbiota to short-chain organic acids, in theory prohibiting the growth of pathogenic ammonia-producing bacteria and facilitating the growth of normal flora.[117] Non-absorbable disaccharides also exert a laxative effect and the dose should be titrated to result in 2–3 bowel movements per day.[124] In patients not absorbing enterally, lactulose can be given as an enema (although this is not available in the United Kingdom). Although the existing evidence base for the use of non-absorbable antibiotics – such as rifaximin – is for the prevention of further episodes of HE, they can be used as second-line agents for the treatment of HE.[125] Other considerations include withdrawal of causative medications, for example stopping proton pump inhibitors (PPIs) unless they are clearly indicated. As with ALF, intubation should be considered for airway protection in higher grades of HE.[126] Unlike ALF however, patients with ACLD are less prone to intracranial hypertension. Therefore neuroprotection and haemofiltration to reduce serum ammonia are not routinely recommended.[127,128]

Coagulation

Interpretation of traditional coagulation tests is a challenge in patients with ACLD. Prolonged prothrombin time (PT) and thrombocytopenia are common in these patients. Historically, it was believed that all these patients were at increased risk of bleeding complications. However, it is now apparent that traditional testing is poorly predictive of bleeding risk.[129] Prolongation of PT and the partial thromboplastin time in patients with ACLD reflect reduced hepatic synthesis of proteins acting as procoagulant factors. However, they fail to measure the concomitant decrease in production of anticoagulant factors such as anti-thrombin, protein C and protein S.[130,131] Thrombocytopenia occurs in cirrhosis due to splenic sequestration of platelets and reduced hepatic production of thrombopoietin.[132,133] However, levels of von Willebrand factor (vWf) are increased in ACLD, supporting platelet function. A balanced homeostasis of coagulation develops, with reduced but balanced levels of both pro- and anticoagulant factors, and the effect of thrombocytopenia tempered by increased vWf and reduced levels of ADAMTS13. [134]

Clinicians should generally avoid correction of coagulopathy in patients with ACLD in the absence of bleeding. We do recommend the administration of vitamin K to patients with prolonged PT as these patients are at high risk of nutritional vitamin K deficiency.

In practice, viscoelastic testing is useful. These point-of-care tests better represent the in vivo clotting profile and peri-procedural bleeding risk of patients. [135] Use of TEG to guide blood product administration has been shown to reduce transfusion in three RCTs in patients with ACLD. [136-138]

In patients with decompensated ACLD who are actively bleeding, we recommend the following targets: haemoglobin of 7–9 g/dL, platelets greater than 50,000/dL and fibrinogen level of 120–150 mg/dL. [139-143]

For low-risk procedures such as paracentesis or central line placement, routine correction of thrombocytopenia or coagulopathy is not recommended. In higher-risk procedures such as lumbar puncture, major surgery or ICP monitor placement, pre-procedural viscoelastic testing and replacement of platelets to >50,000/dL and fibrinogen to 1–1.5 mg/dL is a pragmatic approach. However, guidance for correction of coagulopathy varies, and studies have rarely included critically ill patients with cirrhosis undergoing procedures. [144] FFP should be avoided given its large volume and the associated risk of transfusion-associated circulatory overload and increased portal pressure. [144], [145]

Gastrointestinal System/Nutrition

Protein-energy malnutrition is estimated to affect 75%–90% of patients with ACLD. [146] Its presence is associated with other complications such as ascites, variceal bleeding, impaired wound healing, reduced hepatic function and increased overall mortality. [147] The presence of significant malnutrition and sarcopenia can also impact eligibility for transplant. Stable and critically unwell patients should all undergo a formal nutritional assessment by a registered dietician or nutrition expert. Decompensated patients with cirrhosis should receive at least 35 kcal/kg per day with a protein intake of 1.2–1.5 g/kg/day.[148]

In critically ill patients, feeding should be considered early via the enteral route. Importantly, enteral feeding is not contra-indicated by the presence of varices and may have a role in restoring the intestinal mucosa and potentially reducing levels of bacterial translocation, therefore reducing further inflammation.[149], [150] Early parenteral nutrition (at less than seven days in ICU) is associated with higher rates of infection.[151]

Intra-abdominal hypertension (IAH) – intra-abdominal pressure of >12 mm Hg – is more common in patients with ACLD who are critically unwell with sepsis than in the general ICU population, occurring in up to 82% of patients.[152], [153] Clinical symptoms include nausea, large-volume diarrhoea, abdominal distension and high gastric-residual volumes. Clinical examination is unreliable for diagnosis of IAH and therefore in patients where it is suspected or who have risk factors for its development, abdominal pressures should be frequently monitored by the modified Kron technique.[154], [155] European guidelines suggest that enteral nutrition should not be delayed or discontinued due to diarrhoea or absence of bowel sounds. Enteral nutrition can be continued in the presence of IAH, although abdominal pressures should be monitored closely. If there are concerns that intra-abdominal compartment syndrome has developed, CT abdomen and pelvis should be performed to exclude complications such as gut ischaemia or perforation. Management of IAH should focus on decompression of the abdomen (via nasogastric tube or per rectum), and drainage of ascites with paracentesis.[156] Intra-abdominal wall compliance can also be improved with a trial of neuro-muscular blockade or a trial of neostigmine. Open abdominal decompression is associated with high mortality rates.

PPIs are commonly used as prophylaxis against stress ulcers in patients in intensive care. Their use is associated with increased rates of spontaneous bacterial peritonitis, *Clostridium difficile* infection, HE and other infections.[157-161] The indication for their use should therefore be carefully considered, although they are associated with reduced all-cause mortality in patients hospitalised with gastrointestinal bleeding.[162]

Endocrine System

Adrenal insufficiency in patients with ACLD was first described in 2005.[163] The mechanisms behind this are not confirmed but are likely due to altered hepatic handling of cholesterol, splanchnic vasodilation leading to chronic adrenal hypoperfusion and the suppressive effects of pro-inflammatory cytokines on the hypothalamic-pituitary-adrenal axis.[164, 165] Clinicians should have a low threshold for suspecting adrenal insufficiency in patients with cirrhosis as it may be associated with a reduced response to vasopressors.[166] There is no evidence for routine prescription of steroids outside the setting of septic shock.

Decompensation: Causes, Manifestations and Management

Decompensation in patients with ACLD marks an important progression point in disease severity and a worsening of prognosis. Median survival after an episode of decompensation is two years, compared to 12 years for patients with compensated disease. Decompensation is characterised by the development of jaundice, ascites, variceal haemorrhage or HE.[167] These represent the progression of ACLD and the development of portal hypertension, with ascites and varices developing at portal pressures >10 mm Hg, and variceal bleeding becoming a risk at pressures of >12 mm Hg.[168-170] Common precipitants for decompensation include infection, gastrointestinal bleeding, alcohol excess, alcohol-related hepatitis and drug-induced liver injury.

Ascites and spontaneous bacterial peritonitis

Development of ascites is associated with a reduction in 5-year survival from 80% to 30%.[100, 171] It is the most common cause of decompensation, occurring due to renal sodium retention from renin-angiotensin-aldosterone system and sympathetic nervous system activation. The presence of new ascites should prompt investigation for its aetiology. A sample of ascites should be obtained and sent for biochemistry to determine the serum-ascitic albumin gradient, as well as for microscopy and bacterial culture. 10 mL of ascitic fluid should be inoculated into blood culture bottles to enhance sensitivity. Other tests such as cytology, amylase and culture for mycobacteria should be considered depending on the clinical context. Liver imaging with ultrasound Doppler should be performed to ensure patent hepatic vasculature. Transthoracic echo should be considered to exclude cardiac failure. Standard management of patients with ascites includes sodium restriction and initiation and up-titration of diuretics. First-line diuretics are mineralocorticoid receptor antagonists such as spironolactone, with loop diuretics added as the second line.[94] In critically ill patients, renal injury commonly co-exists, and it may not be appropriate to start or continue diuretic therapy. Indeed, accumulation of ascites may be more rapid in patients admitted to the ICU where resuscitation with fluids or blood products has been required. Management options for ascites include paracentesis with replacement of albumin (100 mL of 20% human albumin solution per 2 L ascites drained) to minimise fluid shifts and haemodynamic instability, and consideration of TIPS in patients with refractory ascites. However, TIPS is more usually undertaken in an outpatient or ward-based setting. Non-selective beta blockers are associated with increased mortality in patients with refractory ascites.[172] Beta-blocker dose reduction or cessation should be considered in the presence of refractory ascites when hypotension, raised serum creatinine or hyponatraemia are also present.

Spontaneous bacterial peritonitis (SBP) is the most common source of bacterial infection in patients with ACLD[173] It should be excluded in all patients presenting with deterioration, decompensation, or signs of infection. An ascitic fluid neutrophil count of greater than 250 cells/mm^3 is diagnostic for SBP. Prompt diagnosis is essential: in those receiving delayed paracentesis more than 12 hours after presentation, there is a 2.7-fold increased risk of mortality. Each hour delay beyond 12 hours is associated with a 3.3% increase in in-hospital mortality.[174] Likewise, mortality increases by 10% for every hour that treatment with antibiotics is delayed.

Most cases of SBP are caused by Gram-negative aerobic organisms, particularly *Klebsiella pneumoniae* and *Escherichia coli* .[175] Initial treatment should be with empiric antibiotics such as third-generation cephalosporins, with choice guided by local resistance patterns and individuals' previous microbiology samples. Multi-drug resistant organisms should be considered, especially in the setting of poor response to antibiotics and antibiotic therapy should be reviewed with blood and ascitic fluid culture results.

Albumin should also be given to patients with SBP: 1.5 g/kg of 20% human albumin solution on day 1 of treatment, and 1 g/kg on day 3.[176] Repeat paracentesis after 2 days of treatment may be helpful to assess response to treatment.[100] Following the resolution of an episode of SBP, antibiotic prophylaxis should be commenced in patients at high risk of further episodes of SBP.[177]

Variceal haemorrhage

Mortality due to variceal bleeding has fallen over the past 50 years.[178] This is attributable to improvements in treatment such as the use of vasoactive agents and endoscopic therapies over balloon tamponade and the use of antibiotics as standard in patients with variceal bleeding. Nevertheless, gastrointestinal bleeding in patients with ACLD remains a common cause of ICU admission and is associated with a high mortality of up to 20%.[179]

The initial approach to patients with suspected variceal bleeding is stabilisation and resuscitation. Volume status should be monitored and restored to optimise tissue perfusion. Patients with massive bleeding should receive a blood transfusion. In haemodynamically stable patients, a restrictive transfusion policy with a target haemoglobin of 70–80 g/L should be used as over-transfusion may be harmful.[180] Correction of traditional coagulation parameters in patients with acute variceal bleeding remains controversial. In patients with ongoing variceal bleeding, there is no evidence that platelet count or fibrinogen levels are correlated with failure to control bleeding or the incidence of re-bleeding.[180] In such cases, platelet transfusion can be considered to target a platelet count of $>50 \times 10^{9}$/L, and in major bleeding replacement of blood products should be performed in line with local policies.[181] Viscoelastic tests can be used to guide blood product replacement. FFP should be avoided as it worsens portal hypertension. As part of assessment and stabilisation, it may be necessary to perform endotracheal intubation in patients in whom the airway cannot be maintained or is at risk, for example patients with altered consciousness or who are actively vomiting blood.

Vasoactive medications such as terlipressin, somatostatin or octreotide should be started as soon as variceal bleeding is suspected and continued for 2 to 5 days, depending on whether haemostasis has been successful. [182] Starting vasoactive drugs before endoscopy reduces bleeding and facilitates endoscopic therapy. Antibiotic prophylaxis to cover Gram-negative infection should also be initiated as soon as variceal bleeding is suspected. [183] These have been shown to increase survival after variceal haemorrhage and reduce bacterial infections and early re-bleeding. Antibiotic selection should be guided by local resistance patterns: 3rd-generation cephalosporins are commonly used in this situation.

Endoscopic therapy should be undertaken after haemodynamic resuscitation, ideally within 12 hours of presentation or as soon as possible in unstable patients. Endoscopic therapies include variceal band ligation, sclerotherapy and haemostatic powder. If these are unsuccessful in controlling bleeding, balloon tamponade can be used with the deployment of a Sengstaken-Blakemore tube. This is effective in controlling acute bleeding in up to 90% of patients, although it has the risks of oesophageal ulceration and aspiration pneumonia, as well as a re-bleed rate of around 50% upon balloon deflation. Balloon tamponade can facilitate further resuscitation and transfer to centres with expertise for repeat endoscopy and/or endovascular therapeutic options. The Sengstaken-Blakemore tube can remain in place for a maximum of 48 hours. Self-expandable metal oesophageal stents can be used for uncontrolled bleeding secondary to oesophageal varices and can remain in place for up to two weeks. [184]

Salvage therapy may be required when bleeding cannot be controlled with endoscopic and pharmacological therapy. TIPS can be used as a rescue therapy, and in addition to TIPS, embolisation of varices can also be undertaken by interventional radiologists. [185] There is growing evidence for the use of early TIPS prior to treatment failure, rather than as a salvage option. Pre-emptive TIPS should be considered in cases with a high risk of treatment failure, for example very high hepatic venous pressure gradients (>20 mm Hg), or patients with Child–Pugh class B and C cirrhosis. In a recent meta-analysis, pre-emptive TIPS was shown to reduce mortality, with no significant increase in risk of post-TIPS HE. [186]

Once bleeding is controlled, patients should be extubated as soon as possible after endoscopy. Lactulose should be given either enterally or via enema to treat and prevent HE. Oral nutrition should be started as malnutrition increases the risk of adverse events. Medications should be reviewed – in particular, PPIs started before endoscopy should be discontinued unless there is another clear indication. Secondary prevention with non-selective beta blockade to reduce portal pressures should be started when haemodynamic status allows for reducing the risk of further variceal bleeding if TIPS has not been performed.

Acute alcohol-related hepatitis

Acute alcohol-related hepatitis is a frequent cause of decompensation in patients with ACLD. [187] Alcohol has a directly toxic effect on hepatocytes. Its metabolism leads to increased oxidative stress and subsequent hepatocyte apoptosis and necrosis. Damage-associated molecular patterns released from dead hepatocytes activate inflammatory processes that cause further cellular injury. [188] Alcohol-related hepatitis is diagnosed when there is recent development of jaundice in patients with ongoing heavy alcohol intake, and elevated serum bilirubin. [189] Other causes of acute hepatitis (e.g. viral) should be excluded, and a liver biopsy may be required if diagnosis is unclear. Infection commonly occurs together with alcohol-related hepatitis and has a negative impact on prognosis. [190]

The severity of alcohol-related hepatitis is assessed using the Maddrey discriminant function, with a score greater than or equal to 32 being severe. [191] Patients with a MELD score between 25 and 39 or with a neutrophil-lymphocyte ratio between 5 and 8 may benefit from corticosteroids. [192], [193] These are contra-indicated in the presence of uncontrolled infection. [194] Response to steroids at seven days can be assessed using the Lille score. A score of >0.45 suggests no response to steroids and a high short-term mortality. A score of <0.45 suggests a response and in this case, steroids should be continued for up to 28 days. [195]

Acute-on-chronic Liver Failure

Several consortia have published separate definitions for ACLF; areas of discordance between definitions include the type of acute insult (hepatic vs extrahepatic), stage of underlying liver disease (cirrhosis or chronic hepatitis) and which organ failures should be included as part of the definition.

In the United Kingdom and Europe, the European Association for the Study of Chronic Liver Failure (EASL-CLIF) Consortium diagnosis is increasingly used in clinical practice (Table 54.6). Diagnostic criteria for organ failures are based on a modified version of the SOFA score; CLIF-SOFA score. ACLF occurs in up to 30% of patients with AD and is present in 22.6% of patients on admission with AD. Based on the presence/absence of organ failures, patients can be categorised into four groups that are associated with increasing mortality; no ACLF (90-day mortality; 14.0%), Grade 1 (40.7%), Grade 2 (52.3%) and Grade 3 (79.1%) (Table 54.8).

Table 54.8

Reproduced from Zaccherini G, Weiss E, Moreau R. Acute-on-chronic liver failure: definitions, pathophysiology and principles of treatment. JHEP Rep. 2021;3(1). https://doi.org/10.1016/j.jhepr.2020.100176 .

A four-part model has been proposed to explain its development, characterised by a predisposing event, followed by injury due to this event, and subsequent response to injury, ultimately leading to organ failure. ACLF is differentiated from AD by intense systemic inflammation and oxidative stress. In ex-vivo studies of ACLF, there is reduced TNF-a production and monocyte HLA-DR expression after lipopolysaccharide (LPS) stimulation. [196] Patients with ACLF also have increased numbers of monocytes and macrophages expressing MER receptor tyrosine kinase which, is a strong suppressant of the innate immune response.

Sepsis is the most common precipitant of ACLF. Other important causes include variceal haemorrhage, alcohol-related hepatitis and HBV re-activation. A clear precipitant cannot be identified in 40% of cases. [197] The risk of fungal infection should be considered. [198]

General points

The aim of the intensive care physician looking after patients with ACLF is to proactively identify and treat precipitants of ACLF and support failing organ systems, either whilst the original insult resolves or until a patient can undergo liver transplantation. Patients with ACLF have generally been considered to have poor prognosis, and there has traditionally been reluctance to admit these patients to the ICU for multi-organ support. Indeed, it is important to consider factors that indicate futility prior to admission. These include advanced frailty (clinical frailty score of seven or more), co-morbidities associated with very poor short-term prognosis, biologically elderly patients unsuitable for liver transplantation and advanced neoplasm. A reasonable approach when deciding which patients to admit will include (1) an appropriate indication (organ support requirement, massive bleeding and severe encephalopathy), (2) the absence of contraindications, (3) a multi-disciplinary approach involving disease specialists and (4) a trial of organ support and subsequent re-evaluation of prognosis.

There should be a low threshold for discussion with local liver transplantation centre to guide management, advise on further investigation and determine whether a patient might be suitable for liver transplantation assessment and transfer to a specialist centre. Admission to a dedicated liver transplantation centre has been associated with a 20% reduction in 28-day mortality, although it is not clear whether this effect is due to specialist management or the availability of liver transplantation. [199]

Six-month mortality for patients surviving an episode of ACLF in critical care is up to 50%. These patients should therefore be followed up closely and this follow-up should include an early assessment of suitability for liver transplantation. For patients who deteriorate and are not suitable for liver transplantation, palliative care should be involved for symptom management and psychological support.

Specific considerations for the management of ACLF are listed in Box 54.5 .

Box 54.5

Specific considerations for the management of ACLF

Airway

- Intubation and mechanical Ventilation for a GCS ≤ 8 or grade 3 or 4 HE

Breathing

- Paracentesis for tense ascites or pleural aspiration of HH if affecting gas exchange
- Transthoracic echo to estimate pulmonary pressures if suspected pulmonary hypertension
- Consider right heart catheterisation if unexplained hypoxia or a high suspicion of pulmonary hypertension in patients where liver transplantation is being considered

Circulation

- Accurate assessment of volume status and fluid responsiveness is challenging
    - Patients may demonstrate a blunted tachycardia response to hypotension due to administration of non-selective beta blockade
    - Markers of hypoperfusion such as lactate or SVO_2 can be difficult to interpret
    - Cardiac output monitoring and transthoracic echocardiography are especially useful for assessment of cardiovascular status
- Balanced crystalloids should be used for fluid resuscitation, with the addition of vasopressors in patients who are not fluid responsive
    - No RCT evidence for the benefit of human albumin solution outside accepted indications of paracentesis, HRS and SBP
    - Vasopressin should be given in addition to noradrenaline in patients who remain hypotensive
    - Low threshold for administration of steroids (hydrocortisone) in patients with refractory hypotension, given the incidence of AI in patients with cirrhosis

Disability

- Serum ammonia measurement in patients with altered consciousness can be useful; although elevated levels do not correlate with severity of HE
- Normal ammonia levels should prompt investigation for other causes of neurological dysfunction such as intracranial pathology, delirium, or metabolic encephalopathy
- Lactulose should be initiated and titrated to achieve 2–3 bowel movements per day to treat and prevent HE
- Intracranial hypertension is rarely a feature of ACLF – unlike ALF; therefore RRT to lower ammonia is usually not indicated
- If sedation is required, short-acting agents should be used. Sedation should be minimised to allow ongoing neurological assessment
- Benzodiazepines should be avoided as they are metabolised by the liver and their action may be prolonged in ACLF

Renal

- Initial approach should include:
  - withdrawal of nephrotoxic medications and diuretics,
  - correction of volume status,
  - vasopressor support for hypotension to ensure adequate renal perfusion,
  - treatment of precipitating events such as infection
- HRS-AKI should be considered if there is no response to these measures, and specific management with albumin and terlipressin initiated
- Consider early initiation of RRT, especially in patients with volume overload

Gastrointestinal

- Early initiation of nasogastric feeding to maintain gut-barrier function
- Addition of pro-kinetics if there is gastric stasis or ileus

- Avoid constipation; regular lactulose and addition of enemas if required
- Drain ascites if contributing to impaired ventilation, AKI, or IAH and potential bowel ischaemia

Coagulation/haematology

- Routine correction of coagulopathy should be avoided in the absence of bleeding, as this may mask important changes in liver function
- Large volume transfusion of blood products may increase portal pressures or contribute to volume overload
- Viscoelastic tests should be used to guide product replacement when required in the context of high-risk procedures or active bleeding
- Restrictive transfusion threshold with a haemoglobin target of >7g/dL
- No specific target for platelet transfusion, although in general platelet count $<20 \times 10^9$/L should be addressed to avoid spontaneous bleeding

Infection

- Infection should be actively sought and broad-spectrum antibiotic therapy initiated as early as possible
- Fungal infection should also be screened for as their presence is associated with a high short-term mortality
- Early antifungal therapy should be initiated in patients with shock

Liver transplantation for ACLF

Patients with ACLF were often previously excluded from liver transplantation due to the perceived futility, however, with careful patient selection there is a significant survival advantage in offering expedited access to organs.[200] Assessment of suitability for liver transplantation should be undertaken in conjunction with hepatologists, transplant surgeons, anaesthetists and intensive care physicians, and must be completed rapidly in order not to miss the window for liver transplantation. Combined European registry data suggests that patients with multi-drug resistant infections and those with a persistently elevated lactate >4 mmol/L have an extremely poor short-term prognosis.[201] The SALT-M score can help identify patients whose risk factors are associated with inadequate post-liver transplantation survival and who should not be listed. Patients with a greater number of organ failures prior to liver transplantation have longer intensive care admissions and more post-operative complications.

Liver-specific therapies

Extracorporeal liver support devices aim to replicate the functions of the liver. Non-biological systems aim to detoxify the blood, whilst biological systems aim to also provide liver synthetic and metabolic functions. Although safety has been demonstrated for systems such as Molecular Adsorbent Recirculating System (MARS), Prometheus and DIALIVE, studies are yet to show evidence of survival benefits in patients with ACLF.

Promising therapies under investigation include mesenchymal stem cell infusion – associated with increased survival in patients with ACLF secondary to HBV and granulocyte colony-stimulating factor – associated with increased 60-day survival in patients with ACLF.[202]

Acute kidney injury

Emily J. See and Rinaldo Bellomo

Introduction

Acute kidney injury (AKI) is a common complication of critical illness and a therapeutic challenge for the intensivist. The term AKI was introduced to emphasise a gradation of dysfunction and abnormality that begins long before kidney ‘failure’ occurs.[1] AKI describes a heterogeneous clinical syndrome characterised by a rapid decrease in glomerular filtration rate (GFR) that occurs over hours to days. This manifests as the accumulation of small and middle molecular weight solutes (including creatinine, urea, potassium and acidifying molecules) and/or decreased urine output, which may or may not be accompanied by fluid overload. More recently, an additional manifestation of interest is the release of biomarkers of injury into the urine.[2,3] The role of such biomarkers in AKI diagnosis and prognosis continues to evolve.

Assessment of Renal Function

Direct measurement of GFR using inulin or iohexol clearance is impractical in the clinical context. Therefore indirect assessment of GFR is performed through the measurement of serum creatinine (or cystatin C) level in blood and the use of specialised equations. However, creatinine and cystatin C are insensitive markers of GFR in the setting of AKI and are heavily modified by many external factors, including the dilutional effect of intravenous fluids[4]. Furthermore, they typically become abnormal after approximately

50% of GFR is lost. More advanced indirect techniques, such as 24-hour urinary creatinine clearance or radionucleotide scanning, may more accurately reflect GFR but are cumbersome and rarely change clinical management and so are infrequently performed.

Definition of Acute Kidney Injury

Three consensus definitions of AKI using indirect assessment of GFR have been published since 2004: RIFLE, AKIN and KDIGO. AKI is currently defined using the KDIGO criteria according to changes in serum creatinine level, urine output and/or the requirement for acute renal replacement therapy (RRT; Table 55.1).[5] It can be further categorised into phenotypes based on its severity and whether injury is transient (<48 hours) or persistent (≥48 hours to 7 days). AKI that is present for more than 7 days is referred to as acute kidney disease.[6] Using consensus definitions, AKI occurs in as many as 30% to 50% of critically ill patients.[7,8]

Table 55.1

KDIGO classification of acute kidney injury

Stage 1	Increase in serum creatinine to 1.5 to 2.0 × baseline over 7 days; *or* Rise in serum creatinine ≥26.5 μmol/L over 48 hours; *or* Urine output <0.5 mL/kg/h for 6 hours
Stage 2	Increase in serum creatinine to 2.0 to 3.0 × baseline over 7 days; *or* Urine output <0.5 mL/kg/h for 12 hours
Stage 3	Increase in serum creatinine to ≥3.0 × baseline over 7 days; *or* Increase in serum creatinine to ≥354 μmol/L with an acute rise ≥26.5 μmol/L *or* Urine output <0.3 mL/kg/h for ≥24 hours or anuria for 12 hours *or* Initiation of renal replacement therapy

Clinical Classification

The most practical approach to the aetiological classification of AKI is to divide its causes according to the probable site of injury: pre-renal, renal (intrinsic) or post-renal.

Pre-Renal Acute Kidney Injury

Pre-renal AKI is by far the most common form in the intensive care unit (ICU) and is considered, at least in its initial phases, to be *functional* in nature (i.e. there are no histopathological changes to renal tissue). It is predominantly due to processes outside the kidneys, which contribute to decreased GFR in pre-renal AKI, including sepsis, hypovolaemia, hypotension, cardiopulmonary bypass and administration of nephrotoxic drugs such as diuretics. If the specific causes of pre-renal AKI are rapidly removed or treated, kidney function quickly improves. However, if intervention is delayed or unsuccessful, renal injury may become established and damage may persist for several days or weeks. In the past, several urine tests (measurement of urinary sodium, fractional excretion of sodium and other derived indices) have been promoted to help clinicians differentiate between *functional* and *established* pre-renal AKI. Unfortunately, their accuracy is doubtful [9] and their clinical utility is negligible. [10]

Renal (Intrinsic) Acute Kidney Injury

Intrinsic AKI describes clinical contexts where the principal source of damage is within the kidney parenchyma and where *structural* changes can be seen on microscopy. Disorders which affect the glomeruli or renal tubules can be responsible (Table 55.2). Amongst these, exogenous (e.g. nephrotoxic drugs) or endogenous (e.g. rhabdomyolysis) nephrotoxins are particularly important, especially in the ICU.

Table 55.2

Causes of intrinsic acute kidney injury

Glomerulonephritis
Interstitial nephritis
Vasculitis
Malignant hypertension
Thrombotic microangiopathy
Pre-eclampsia
Pyelonephritis
Bilateral cortical necrosis
Amyloidosis
Malignancy
Nephrotoxins
Cholesterol embolism

The most common nephrotoxic drugs affecting ICU patients are listed in Table 55.3 . Many cases of drug-induced AKI rapidly improve upon the removal of the offending agent. Accordingly, a careful history of drug administration is *mandatory* in all patients with AKI. However, some drugs can initiate specific immune-mediated processes within the kidney (e.g. acute interstitial nephritis) that require further investigation and treatment. For many patients, the correct working diagnosis can be obtained from history, physical examination and review of laboratory investigations. However, if immunosuppressive therapy is being considered, renal biopsy is recommended.

Table 55.3

Drugs which may contribute to acute kidney injury in the intensive care unit

Radiocontrast agents
Starch continuing fluids
Aminoglycosides
Amphotericin
Non-steroidal anti-inflammatory drugs
Sulphonamides
Antivirals (acyclovir, ganciclovir)
Methotrexate
Cisplatin
Lithium
Calcineurin inhibitors
mTOR inhibitors
Renin-angiotensin system (RAS) inhibitors
Methotrexate
Vancomycin

The terms acute tubular necrosis (ATN) and pre-renal azotaemia warrant specific discussion. ATN is often used by textbooks and clinicians to describe a form of intrinsic AKI that follows severe and/or persistent pre-renal AKI. However, this use of the term is misleading since ATN conflates a histopathological diagnosis (i.e. necrosis of tubular epithelial cells) that is rarely confirmed by biopsy. Moreover, the histopathological diagnosis of ATN has *not* been convincingly linked with severe and/or persistent pre-renal AKI either in animal experiments or in human disease.[11, 12]

Conversely, it is similarly inaccurate to refer to this state as pre-renal azotaemia because this implies that clinicians can know with a sufficient degree of certainty based on history, examination and laboratory investigations that there is no histopathological injury to the tubules. [13, 14] For all of these reasons, terms like ‘ATN’ and ‘pre-renal azotaemia’ are increasingly being challenged in favour of the more accurately representative syndrome and spectrum of AKI. [10, 13]

Post-Renal Acute Kidney Injury

Obstruction to urine outflow is the most common cause of functional renal impairment in the community, [15] but is uncommon in the ICU due to the frequent use of indwelling urinary catheters in critically ill patients. However, post-renal AKI can occur in the context of renal tract obstruction due to the presence of renal calculi. This is usually unilateral and so may not always be associated with oliguria. If obstruction is suspected, ultrasonography can be easily performed at the bedside. However, not all cases of acute obstruction have an abnormal ultrasound, and, in many cases, obstruction occurs in conjunction with other renal insults (e.g. staghorn calculi complicated by severe urosepsis). Patient assessment and management should be conducted in conjunction with a urologist. Beyond calculi, the sudden and unexpected development of anuria in an ICU patient should always suggest obstruction of the urinary catheter as a possible cause. Appropriate flushing or changing of the catheter should be trialled in this setting.

Specific Acute kidney injury syndromes

Hepatorenal Syndrome

Hepatorenal syndrome (HRS) is a form of AKI, which occurs in the setting of severe advanced liver dysfunction and in the absence of other known intrinsic causes of AKI. [16] Typically, it presents as progressive oliguria with a very low urinary sodium concentration (<10 mmol/L). Its pathogenesis is not well understood; however, reduced renal blood flow due to vasodilatation of the splanchnic circulation in the context of portal hypertension is thought to play a central role. Important contributors to its pathogenesis include sepsis, spontaneous bacterial peritonitis, raised intra-abdominal pressure due to tense ascites, paracentesis-induced hypovolemia, diuretic-induced hypovolemia and lactulose-induced hypovolemia. In the past, the presence of these contributors was used to exclude HRS; however, recent consensus definitions have incorporated them as common triggers of disease. [16]

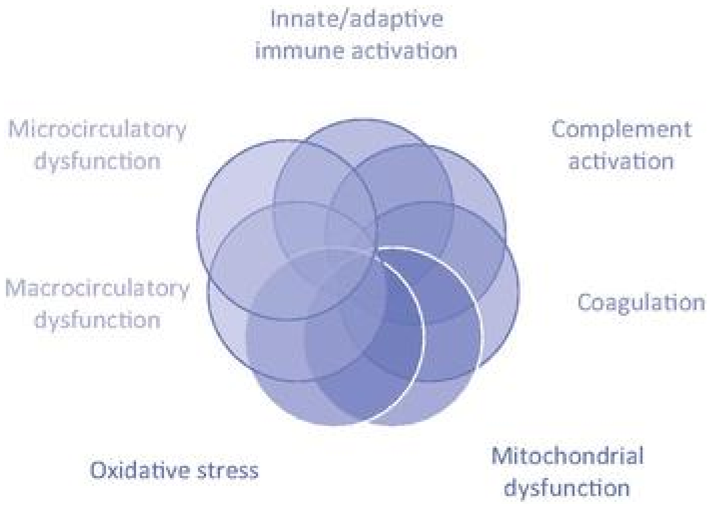
The prognosis of HRS is guarded in those patients who are ineligible for liver transplantation. Avoidance of hypovolaemia by albumin administration in patients with spontaneous bacterial peritonitis has been shown to decrease the incidence of HRS. [17] Vasoconstriction of the splanchnic circulation through terlipressin (ward or ICU) or noradrenaline (ICU) improves GFR in HRS. [18], [19] For refractory cases, the use of transjugular intrahepatic portosystemic shunt may improve HRS outcomes but has not been studied in randomised controlled trials. In eligible patients, RRT may be required as a bridge to liver transplantation. The role of RRT in patients who are not candidates for liver transplantation is controversial and centre-dependent.

Rhabdomyolysis-Associated Acute Kidney Injury

Rhabdomyolysis contributes to between 5% and 10% of cases of AKI in the ICU depending on the case mix. [20] It is typically seen following major trauma, long periods of immobility on hard surfaces, prolonged seizure activity, vascular embolism or in response to a variety of agents which can induce major muscle injury (e.g. statins and snake venom). The principles of treatment are based largely on retrospective data. They include prompt and aggressive fluid resuscitation, elimination of causative agents, release of tissue compartments (where indicated), alkalinisation of urine ($pH > 6.5$) and maintenance of polyuria (>300 mL/h). Loop diuretics have not been shown to be effective in the prevention of rhabdomyolysis-associated AKI but may be given to patients who develop hypervolemia in the context of fluid administration.

Pathogenesis of Acute Kidney Injury

The pathogenesis of AKI is complex and poorly understood. Indeed, much of our understanding is derived from animal models that use ischaemia induced by the acute and complete occlusion of the arterial vascular supply to the kidney.[21,22] Unfortunately, such models bear little resemblance to the human clinical phenotype of AKI, especially in the ICU.[23,24] However, the contemporary paradigm of AKI pathogenesis is that multiple mechanisms of injury occur simultaneously, with the dominant mechanism(s) reflecting the nature of the insult (Fig. 55.1). Key mechanisms that are believed to contribute to many cases of AKI include immune activation (innate immune system, adaptive immune system and complement pathways), disturbances of the macrocirculation and microcirculation and metabolic reprogramming (reprioritisation of energy expenditure, shift from aerobic glycolysis to oxidative phosphorylation and restoration of mitochondrial pool).



Innate/adaptive immune activation
Complement activation
Coagulation
Mitochondrial dysfunction
Oxidative stress
Macrocirculatory dysfunction
Microcirculatory dysfunction

A Venn diagram represents interconnected mechanisms in disease pathology. The labelled factors include innate or adaptive immune activation, complement activation, coagulation, mitochondrial dysfunction, oxidative stress, macrocirculatory dysfunction, and microcirculatory dysfunction. The factors overlap in the centre, forming a complex interaction and shared pathways between these processes.

FIG. 55.1 Schematic representation of contributors to the pathogenesis of acute kidney injury in the intensive care unit.

Despite their shortcomings, animal models have provided some insights into the pathogenesis of AKI. In a large animal model of hyperdynamic sepsis, renal blood flow was found to increase (rather than decrease) in the presence of AKI and renal histopathology was essentially normal. [25], [26] This goes against the traditional paradigm that AKI in sepsis occurs due to hypoperfusion and causes necrosis of tubular cells. Moreover, kidney ATP levels were found to be highly preserved. It is impossible to know for sure whether this also occurs in humans. Disturbances in the functions of the renin-angiotensin system (RAS), renal sympathetic system [27] and tubulo-glomerular feedback (TGF) system have also been implicated by animal models in the pathogenesis of AKI. [28] Such abnormalities may contribute to intra-renal shunting and subsequent ischaemia of the renal medulla. [29]

The Clinical Picture

The most common clinical picture of AKI seen in the ICU is that of a patient with one or more major systemic insults (e.g. sepsis, myocardial infarction, cardiogenic shock, severe haemorrhage, trauma or major surgery). When the patient arrives in the ICU, resuscitation is likely to be well under way or surgery could have just been completed. Despite such efforts, the patient may already be anuric or oliguric, the serum creatinine may be rising and metabolic acidosis may be developing, sometimes with accompanying hyperkalaemia.

In the ICU, fluid resuscitation is typically undertaken under the guidance of invasive haemodynamic monitoring (central venous catheter, arterial cannula and pulmonary artery catheter or pulse contour cardiac output catheters or echocardiography in some cases). Once fluid resuscitation is adequate or simultaneous to its administration, vasoactive drugs are used to restore mean arterial pressure (MAP) to ‘acceptable’ levels (typically >65–70 mm Hg). The patient may improve over time and urine output may return with or without the assistance of diuretic agents. If urine output does not return, however, RRT may need to be considered. Once the cause of AKI has been identified and removed and the patient has become physiologically stable, slow (days to weeks) recovery typically occurs. If the cause of AKI has not been adequately remedied, the patient will typically remain ill, the kidneys will typically not recover and multi-organ dysfunction may occur.

The Importance of Renal Functional Reserve

Sometimes, the degree of physiological insult(s) contributing to AKI seems disproportionate to the decrease in GFR. This may be explained by renal functional reserve, or the capacity of the kidneys to augment GFR through hyperfiltration in states of acute stress. Renal functional reserve is reduced in patients with underlying chronic kidney disease (CKD), which is present in more than one-third of patients in ICU. Patients without documented CKD can also have reduced renal functional reserve, and such patients can be identified by the presence of CKD risk factors such as older age, hypertension, diabetes or atheromatous disease of the renal vessels.

Preventing Acute Kidney Injury

The fundamental principle of AKI prevention is to treat its underlying cause. If pre-renal factors have contributed to injury, these must be identified and corrected quickly, alongside haemodynamic resuscitation.

Resuscitation

Intra-vascular volume must be maintained or rapidly restored, as guided by invasive haemodynamic monitoring. The nature of volume resuscitation has been the focus of many recent trials. These have shown that the use of synthetic starches (e.g. hydroxyethyl starch) should be strictly avoided, and that balanced electrolyte solutions (e.g. plasmalyte) and albumin do not provide a clear survival or AKI benefit compared to 0.9% saline. [30–32] The need to avoid excessive volume resuscitation has also been found to be critically important: restrictive fluid balance in critically ill patients with AKI may reduce adverse events. [33]

Alongside fluid management, other elements of resuscitation also warrant attention. Adequate oxygenation levels must be maintained and a haemoglobin concentration of at least >70 g/L should be targeted. Vasopressor therapy should be considered where MAP remains <65–70 mm Hg despite adequate fluid-based resuscitation. Below this value, autoregulation of renal blood flow may be lost and restoration of MAP to such levels may increase GFR. [34] Where cardiac output is inadequate, a variety of interventions may be required from the use of inotropic drugs to the application of ventricular assist devices.

Nephroprotective Drugs

Following resuscitation, it is unclear whether the use of additional pharmacological measures is of further benefit to the kidneys. A phase III trial in critically ill patients showed that low-dose dopamine is no more effective than a placebo in the prevention of renal dysfunction in ICU patients. [35] The use of loop diuretics is controversial and not supported by high-quality evidence. Other agents such as *theophylline, urodilatin, anaritide* (a synthetic atrial natriuretic factor) or *fenoldopam* have failed to show consistent benefits. In patients receiving radiocontrast, saline infusion to maintain intra-vascular fluid expansion may be helpful in attenuating kidney injury. However, the administration of isotonic sodium bicarbonate or oral n-acetylcysteine did not reduce risk. Several potentially nephroprotective drugs are currently under evaluation.

Diagnostic Investigations

The aetiology of AKI must always be established. Sometimes, it may be obvious on clinical grounds. In other cases, investigations may be needed, including examination of the urine sediment (for blood, protein and infection) and renal tract imaging (for obstruction).

In specific situations, other investigations are necessary to establish the diagnosis, such as creatine kinase and free myoglobin for possible rhabdomyolysis. Drug levels (e.g. vancomycin) may also be indicated. A chest radiograph, blood film, inflammatory marker panel and antibodies screen may help diagnose vasculitis, connective tissue disease or glomerulonephritis. If thrombotic microangiopathy is suspected, measurement of platelet count, lactate dehydrogenase, haptoglobin and unconjugated is needed. In some patients, specific findings (cryoglobulins and Bence Jones proteins) are almost diagnostic. Rarely, a renal biopsy might become necessary.

Novel Biomarkers of Acute Kidney Injury

Using new search techniques based on proteomics, investigators have identified novel biomarkers of AKI. [36] The identification of these biomarkers may influence our diagnosis, classification and treatment of this condition in the future. Firstly, they appear to increase earlier than changes in serum creatinine. [37] Secondly, they appear to reflect different aspects of renal injury. For example, cystatin C reflects changes in GFR; neutrophil gelatinase-associated lipocalin (NGAL) reflects tubular stress/injury, and insulin-like growth factor binding protein 7 and tissue inhibitor of metalloproteinase 2 (IGFBP7-TIMP2) reflect cell cycle arrest. Thirdly, they appear to change dynamically with treatment or recovery, which suggests that they can be used to monitor interventions. Fourthly, they may identify subpopulations of patients who do not have AKI according to standard criteria, but in whom a degree of kidney stress/injury can be detected and is associated with worse outcomes (i.e. subclinical AKI). [37] They may also offer important prognostic information in terms of risk stratification. Finally, by identifying possible mechanisms of injury they may increase our understanding of the pathogenesis of AKI. Their therapeutic implications and clinical utility, however, remain unclear.

Management of Established Acute Kidney Injury

Supportive Care

The principles of managing established AKI are the treatment or removal of its cause, the avoidance of further injury and the maintenance of physiological and haemodynamic homeostasis while recovery takes place. Complications such as encephalopathy, pericarditis, myopathy, neuropathy or other major electrolyte, fluid or metabolic derangements should never occur in a modern ICU. Their prevention may include several measures, which vary in complexity from fluid restriction to the initiation of RRT.

Doses of all drugs administered to a patient with AKI must be reviewed and adjusted (where necessary) to consider the effect of decreased clearance associated with loss of renal function. Stress ulcer prophylaxis and deep vein thrombosis prophylaxis are advisable according to local practices and guidelines. Assiduous attention should be paid to the prevention of infection.

Nutritional support should contain adequate calories (approximately 20 kcal/kg/day) as a mixture of carbohydrates and lipids. Adequate protein (at least 1 g/kg/day) should be administered. There is no evidence that specific renal nutritional solutions are useful in patients with AKI. Vitamins and trace elements should be administered at least according to their recommended daily allowance. The role of immuno-nutritional solutions remains inadequately tested. The enteral route is generally preferred to the use of parenteral nutrition.

Hyperkalaemia and Metabolic Acidosis

Hyperkalaemia (>6 mmol/L) should be promptly treated either with insulin and dextrose; frusemide; bicarbonate (if acidosis is present); or nebulised salbutamol, or all of the above together. Resonium administered orally or rectally may be suitable in some ICU patients depending on clinical context but is rarely justifiable in a modern ICU. If the serum potassium is >7 mmol/L or electrocardiographic signs of hyperkalaemia appear, calcium gluconate (30 mL of 10% solution IV) should also be considered. The presence of severe hyperkalaemia is a major indication for the immediate institution of RRT and the above measures are temporising actions, while the RRT circuit is being set up. Metabolic acidosis is almost always present in AKI but rarely requires treatment per se. A recent pilot study suggests the benefit of bicarbonate infusion but requires validation in a randomised controlled trial powered for efficacy.[38]

Diuretics

Fluid overload can be prevented by the use of diuretics in non-oliguric patients. Loop diuretics (e.g. frusemide and bumetanide) act on the thick ascending limb to block the Na^{+}-K^{+}-$2\mathrm{Cl}^{-}$ channel. This achieves an effective natriuresis of between 20% and 25%, but can cause metabolic alkalosis, hypernatraemia and hypocalcaemia. Thiazide diuretics and potassium-sparing diuretics are often used alongside loop diuretics to further augment natriuresis or to counteract unwanted side effects. Thiazide diuretics (e.g. chlorothiazide, hydrochlorothiazide and chlorthalidone) block the Na^+-Cl^- cotransporter in the distal tubule resulting in a 5% natriuresis. They may cause hyponatraemia. Potassium-sparing diuretics such as amiloride, spironolactone and eplerenone block (or reduce the synthesis of) the sodium transporters in the distal tubule and collecting ducts, contributing to 1%–2% natriuresis. Exposure may lead to hyperkalaemia and metabolic acidosis. Beyond the treatment of fluid overload, administration of loop diuretics may play a role in the prognostication of AKI through a 'frusemide stress test'. Patients who fail to produce adequate urine output in response to a dose of frusemide may be at higher risk of requiring RRT.[39]

Renal Replacement Therapy

Marked uraemia, acidaemia, hyperkalaemia or volume overload are undesirable. If the patient is oliguric and not responsive to diuretics, RRT should be instituted unless recovery is imminent or already underway, with a return toward normal values expected within 24–48 hours. Randomised controlled trials have not found a benefit in terms of survival with the early initiation of RRT for AKI.[40–42] Conversely, early initiation of RRT may increase long-term dialysis dependence.

Prognosis

The mortality of critically ill patients with AKI remains high (30%–50% depending on clinical context). Although it is frequently stated that patients die with AKI rather than of AKI, much indirect evidence supports a careful and proactive approach to AKI treatment to improve patient survival and renal recovery. Approximately 1 in 3 survivors of AKI will have a major adverse kidney event in the first year after hospital discharge,[43] including the 3%–5% of patients who go on to require chronic RRT.[44] Long-term risk applies even to patients in whom baseline kidney function is normal and for whom AKI recovery appears to be complete.[45–47] Accordingly, it seems advisable to refer patients treated in the ICU for severe AKI to follow-up nephrology care.

Renal replacement therapy

Emily J. See and Rinaldo Bellomo

Introduction

When acute kidney injury (AKI) is severe, resolution can take several days or weeks. During this time, the kidneys may be unable to maintain homeostasis of fluid, potassium, uraemic solutes and acid-base status. If this pathophysiological state is prolonged, life-threatening complications can develop and extracorporeal blood purification becomes necessary. Extracorporeal blood purification techniques are broadly referred to as renal replacement therapy (RRT). Modalities of RRT delivered in the intensive care unit (ICU) include continuous renal replacement therapy (CRRT), intermittent haemodialysis (IHD), slow low-efficiency daily dialysis (SLEDD), and peritoneal dialysis (PD). All techniques are based on the movement of solutes and water across a semipermeable membrane via diffusion and/or convection. The semipermeable membrane can be biological (i.e. the peritoneum) or artificial (i.e. haemofiltration membrane). Each technique has its own advantages, disadvantages and limitations.

Principles

The principles of RRT have been extensively studied and described. [1-3] Here we summarise several key aspects, which are relevant to the critical care physician.

Solute removal

The removal of unwanted solutes (uraemic toxins, nitrogen waste products and organic acids) by RRT can be achieved by:

1. *Diffusion* : creating an electrochemical gradient for the movement of solutes across the membrane using countercurrent flow (CRRT or IHD in haemodialysis or haemodiafiltration modes) or serial replacement (PD) of dialysate. The rate of diffusion for a given solute depends on its molecular weight (MW), the porosity of the membrane, the blood flow rate, the dialysate flow rate, the degree of protein binding and the concentration gradient across the membrane. Diffusion clears small molecules like creatinine most effectively (<0.5 kDa).
2. *Convection* : this process works by creating a trans-membrane pressure gradient that drives solutes along with water across the membrane (‘solvent drag’). Solute-rich plasma water is discarded into the effluent and replaced with solute-free replacement fluid (CRRT or IHD in haemodialysis or haemodiafiltration modes). Convection clears middle molecules like β_2 microglobulin (>1 kDa) more effectively than diffusion.

The synthetic high-flux membranes used in contemporary CRRT and IHD have a high cut-off point meaning that molecules with a MW up to 10–20 kDa can be removed. For this reason, both diffusion and convection deliver comparable solute clearance during CRRT. No trials have demonstrated a survival difference between modalities that utilise diffusion (haemodialysis and haemodiafiltration) or convection (haemofiltration and haemodiafiltration).

Water Removal

The removal of excessive water and salt is often as important as the removal of unwanted solutes. During RRT, water is removed through a process called *ultrafiltration* . This process mimics the filtration of plasma water across the glomerulus. Ultrafiltration requires a driving pressure to move water through a semipermeable membrane because such fluid would normally remain within the circulation due to oncotic pressure. This driving pressure is achieved by:

1. A blood pump that generates a *trans-membrane pressure* gradient between the blood compartment and effluent compartment (CRRT, IHD or SLEDD). This positive pressure is greater than the oncotic pressure that would retain water in the circulation, resulting in ultrafiltration.
2. Delivering hyperosmolar dialysate into the peritoneal cavity, which draws water across the peritoneum along an osmolar gradient (PD).

Initiation of Renal Replacement Therapy

The timing of RRT initiation in critically ill patients with AKI has been the subject of multiple randomised controlled trials over the last decade. [4-6] These trials have failed to demonstrate a survival benefit with early initiation of RRT compared to standard initiation of RRT. However, early initiation of RRT was found to be associated with greater overall delivery of acute RRT and greater future requirements for chronic RRT, implying that, in suitable patients, a waiting strategy is preferable. The specific reasons for this latter finding are not entirely clear but may reflect dialysis-induced haemodynamic instability and impairments in organ perfusion. [7], [8] Accordingly, the decision to initiate RRT in critically ill patients with AKI should be guided by such knowledge and clinical judgement. [9], [10] A set of modern criteria which can be considered sufficient for the initiation of RRT in the ICU is presented in Table 56.1 .

Table 56.1

[a] Please be aware of differences between plasma versus serum measurement in your laboratory. Also note that these criteria provide general guidance, and their use must be within the context of clinical judgement.

Modality of Renal Replacement Therapy

There is a great deal of controversy as to which modality of RRT is ‘best’ in the ICU due to the lack of randomised controlled trials.[11], [12] In their absence, modalities of RRT may be judged based on the following criteria:

1. Haemodynamic side effects
2. Ability to control fluid status
3. Ability to control acidosis, hyperkalaemia and uraemia
4. Dialysis access
5. Availability of equipment and trained staff
6. Biocompatibility
7. Risk of infection
8. Cerebral oedema or disequilibrium risk
9. Ability to allow full nutritional support
10. Cost

In relation to the above criteria, CRRT and SLEDD offer many advantages over PD and IHD (4–5 hours/day, 5 times/week).[13] Therefore these modalities are used almost exclusively in Australian and New Zealand ICUs.[14] In other jurisdictions such as the United States or France, however, IHD may be used in 40% to 50% of patients.[5] Irrespective of the choice of modality, some salient aspects of CRRT, IHD and PD, require discussion.

Continuous Renal Replacement Therapy

First described in 1977, CRRT has undergone several technical modifications over the last 40 years. It is now performed using double-lumen catheters and peristaltic blood pumps, which control the ultrafiltration rate. If no dialysate is used and effluent is replaced with substitution solutions, the technique is called continuous veno-venous haemofiltration (CVVH). During CVVH, ultrafiltration rates of 2 L/h yield urea clearances of approximately 25 mL/kg/h in the average 80 kg patient (Fig. 56.1). When dialysate is used to achieve to achieve diffusive clearance of solutes, the technique is referred to as continuous veno-venous haemodialysis (CVVHD) (Fig. 56.2). Techniques of convective and diffusive clearance can be applied simultaneously in continuous veno-venous hemodiafiltration (CVVHDF) (Fig. 56.3).

Effluent

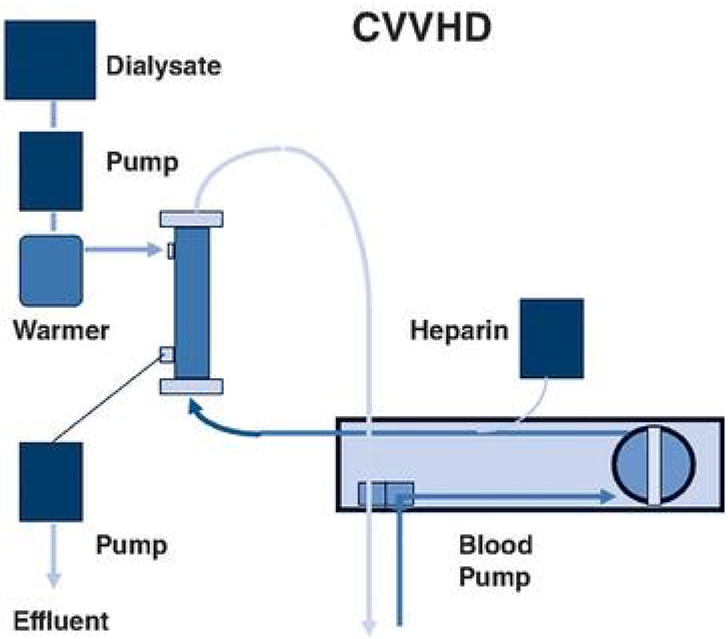
The diagram shows a continuous venovenous haemodiafiltration system. Blood flows through a filter driven by a blood pump, with a citrate-infused pre-filter for anticoagulation and a calcium post-filter. Dialysate and replacement fluids are added via separate I V pumps. A warmer is used before dialysate enters the filter. Effluent exits the filter via another I V pump.

FIG. 56.2 Diagram illustrating a continuous veno-venous haemodialysis circuit (CVVHD).



The diagram shows a continuous venovenous haemodialysis system. A blood pump circulates blood through a filter. Heparin is infused before the filter for anticoagulation. Dialysate is delivered via a pump and passed through a warmer before entering the filter. Waste fluid exits from the filter via another pump.

FIG. 56.3 Diagrams illustrating a continuous veno-venous haemodiafiltration circuit (CVVHDF).

Regardless of the CRRT technique that is used, the following outcomes are predictable:

1. Continuous control of fluid status, osmotically active solutes and acid-base status
2. Haemodynamic stability
3. Ability to provide protein-rich nutrition while achieving uraemic control
4. Control of electrolyte balance, including potassium, phosphate and calcium balance

5. Prevention of swings in intra-cerebral water
6. Minimal risk of infection
7. High level of biocompatibility.

Anticoagulation

The passage of blood through the extracorporeal circuit activates the coagulation cascade, which promotes the clotting of the filter and circuit. Therefore under most circumstances, CRRT mandates the use of continuous circuit anticoagulation. Anticoagulation can be delivered either regionally (within the circuit) or systemically (within the circuit and patient).[15] Since some forms of anticoagulation increase the risk of bleeding, the most appropriate approach for an individual patient must be carefully considered (Table 56.2).

Table 56.2

Regional citrate is the preferred approach to circuit anticoagulation in patients without a contraindication to its use. This approach involves infusion of a citrate-containing fluid as blood enters the CRRT circuit, which chelates calcium and inhibits the clotting cascade. Calcium is reinfused as the blood returns to the patient to ensure that systemic ionised calcium levels remain normal. Compared to other approaches, regional citrate anticoagulation reduces the risk of circuit loss, filter failure, bleeding and heparin-induced thrombocytopaenia.[16, 17] Several randomised controlled trials have established that this approach is the safest and most effective way of preventing clotting within the CRRT circuit.[17, 18] The main contraindications to regional citrate are severe liver failure and hyperlactataemia >5 mmol/L. In such patients, citrate accumulates and induces a coagulopathy, which manifests as an anion gap metabolic acidosis, escalating the requirement for calcium administration to maintain the target ionised calcium, and widening the total calcium to ionised calcium ratio.

When citrate is contraindicated and a patient is at high risk of bleeding, regional heparin/protamine anticoagulation is a reasonable alternative.[18] For patients in whom the risk of bleeding is low, an infusion of low-dose heparin (500–800 IU/h) achieves adequate circuit life, is easy and cheap to administer and has almost no effect on the patient's coagulation tests. Doses of up to 1000–1200 IU/h may be required in some patients to maintain circuit patency. In patients with an indication for systemic anticoagulation (e.g. pulmonary embolism and myocardial ischaemia), administration of therapeutic anticoagulation with either unfractionated or low-molecular-weight heparin is sufficient to prevent filter clotting.

Patients with heparin-induced thrombocytopaenia and thrombosis should receive a heparin-free anticoagulation regimen with either danaparoid, argatroban or bivalirudin. The choice of agent will depend on the centre's preference. In patients with severe coagulopathy (e.g. acute liver failure), CRRT may be delivered without anticoagulation. In such patients, reasonable filter life can be achieved if vascular access is reliable. [19]

Many circuits clot for *mechanical reasons* (e.g. inadequate access, unreliable blood flow and kinking of the catheter). [20] Responding to frequent filter clotting by increasing anticoagulation without identifying and correcting the precipitant is often futile and exposes the patient to unnecessary risk. Smaller (11.5 Fr) catheters in the subclavian position are a particular problem. Larger catheters (13.5 Fr) in the femoral position or internal jugular position appear to perform more reliably. [21]

Continuous Renal Replacement Therapy Technology

The increasing use of CRRT has led to the development of different devices to enhance its safety and performance. [22] Some understanding of these devices is important to the successful implementation of CRRT in any ICU. Modern CRRT machines are safer than early machines with more sophisticated pump control systems, alarms and graphic displays. They are much more user friendly, especially during the set-up procedure. They provide information on access pressure (the suction pressure applied to the outflow lumen of the dialysis catheter and a marker of its performance), trans-membrane pressure (a marker of membrane fouling and clotting) and inflow pressure (a marker of resistance of returning blood to the patient).

Such pressures are often useful in assessing catheter function and the aetiology of circuit loss.[20]

The choice of membrane during CRRT is also a matter of controversy. There are no randomised controlled studies to show that any membrane confers a clinical advantage over others. The AN 69 is the most used CRRT membrane in Australia. This is a synthetic and biocompatible high-flux membrane that can be incorporated into most CRRT circuits. The issue of membrane size is also controversial as no controlled studies have compared different membrane surface sizes. The membrane surface area for standard CRRT is typically 1–1.5 m^2 .

Intensity of Continuous Renal Replacement Therapy

The optimal dose (expressed at effective effluent/kg/h) of RRT has been the subject of controversy for more than a decade. Several studies had initially suggested that higher dose RRT may translate into better outcomes.[23-25] However, such studies were single centre and the generalisability of their findings required confirmation in multicenter trials. Two such trials were completed in 2008[26] and 2009.[27] Both showed no difference with increased intensity of RRT indicating that, in current practice, the prescribed dose of RRT should be approximately 20–25 mL/kg/h. Considering the impact of ‘downtime’ of delivered RRT, a prescribed RRT dose of 25–30 mL/kg/h is recommended. The exception to this is acute liver failure, in which setting a prescribed RRT dose of 40–50 mL/kg/h is often prescribed to control ammonia levels.

Intermittent Haemodialysis

Acute vascular access, circuit setup and available techniques for IHD are the same as CRRT. The major differences between IHD and CRRT are that IHD uses a high blood flow rate (200–400 mL/min), high dialysate flow rate (>400 mL/min), short thrice weekly treatment time (4–5 hours) and generates dialysate ‘on-line’ by mixing purified water and concentrate. These differences have important implications. Firstly, volume needs to be removed over a much shorter period, which may cause hypotension. Repeated hypotensive episodes may delay renal recovery.[4,28] Secondly, solute removal is episodic. This translates into inferior control of uraemic solutes and acid-base status and increases the risk of raised intra-cranial pressure due to rapid shifts in solute concentration and brain water content.[29,30]

The limitations of applying IHD to the treatment of AKI in ICU have led to the development of new approaches (so-called ‘hybrid techniques’) such as SLEDD.[13] These techniques seek to adapt IHD to the clinical circumstances, decrease the rate of volume removal, decrease the rate of solute clearance and thereby increase tolerance and overall clearances. The uptake of SLEDD, however, has been limited by the availability of trained staff and equipment.[26] Consensus statements on the principles and nomenclature for haemodialysis based RRT modalities have been published for reference.[31,32]

Peritoneal Dialysis

This technique is now uncommonly used in the treatment of adult AKI in developed countries but remains relatively common in children and in low-resource settings.[23] In such settings, PD is an inexpensive and minimally invasive RRT technique that can be safely applied where alternatives are too expensive, too invasive or not feasible. Access is achieved by the insertion of a catheter into the peritoneum. Glucose-rich (hypertonic) dialysate is instilled into the peritoneal cavity then drained and discarded after a given ‘dwell time’. PD can be performed manually or by automated machines.

Several major shortcomings make PD less suitable for the treatment of adult AKI:

1. Limited solute clearance
2. High risk of peritonitis
3. Unpredictable hyperglycaemia
4. Fluid leaks
5. Protein loss

6. Interference with ventilation

In developed countries, there is a paucity of evidence on the use of PD for the treatment of adults with AKI. A randomised trial comparing PD to CVVH found that PD was associated with increased mortality. [23] In children, however, especially after cardiac surgery, given the difficulties with vascular access, peritoneal dialysis is frequently and effectively used.

Other Blood Purification Techniques

Haemoperfusion

During haemoperfusion, blood flows through a circuit like CRRT. However, a sorbent cartridge (or in some cases an ion exchange resin) is used instead of a haemofilter. Sorbent beads effectively remove molecules of >300–500 Da in MW, including some lipid-soluble and protein-bound substances. Heparinisation is necessary to prevent clotting. Attention must also be paid to changes in intra-vascular volume at the start of therapy because of the large priming volume of the cartridge (up to 300 mL). A degree of thrombocytopaenia is common and can be marked. The role of haemoperfusion in clinical practice is controversial, as no controlled trials have ever shown it to confer clinically significant advantages. It may be useful, however, in patients with life-threatening toxic overdoses (e.g. theophylline, paraquat and carbamazepine) because it removes several agents effectively. Several studies with polymyxin-bound cartridges aimed at removing endotoxin or with cartridges containing new sorbents capable of removing cytokines ex-vivo have been performed over the last two decades. However, no convincing data has yet emerged that they provide significant clinical benefits. [33]

Plasmapheresis or Plasma Exchange

With this technique, plasma is removed from the patient and exchanged with fresh frozen plasma (FFP) and/or albumin. When performed by a CRRT machine, a plasma filter that allows the passage of molecules up to

500 kDa is used instead of a haemofilter, and the filtrate (plasma) is discarded. Plasma replacement (post-filter) will occur as in CRRT using a combination of FFP and albumin. Plasmapheresis can also be performed with specific plasmapheresis machines that use the principles of centrifugation. The differences, if any, between centrifugation and filtration techniques are unclear. Plasmapheresis has been shown to be effective in the treatment of thrombotic thrombocytopenic purpura (TTP) and several diseases mediated by abnormal antibodies (Guillain-Barre syndrome, cryoglobulinemia, myasthenia gravis, anti-GBM disease, ANCA vasculitis etc.) in which antibody removal appears desirable. For further information on plasmapheresis and plasma exchange refer to Chapter 108 .

Blood Purification Technology Outside of Acute Kidney Injury

There is growing interest in the possibility that blood purification could provide clinically significant benefits in patients with severe sepsis/septic shock through the removal of circulating 'mediators'. A variety of techniques including haemadsorption membranes, plasmapheresis, high-volume haemofiltration, very-high-volume haemofiltration, coupled plasma filtration adsorption and large pore haemofiltration have been studied. [33-38] However, results to date have failed to show any benefit in terms of patient-centred outcomes. [39] In patients with liver failure, albumin-based dialysis has been developed to deal with protein-bound toxins. This system known as molecular adsorption re-circulating system (MARS) has shown limited benefits in patients with elevated intra-cranial pressure and/or acute-on-chronic liver failure, but not in patients with fulminant liver failure. Thus it has not become an established therapy. [40] Investigations into novel liver dialysis devices (e.g. DIALIVE) in patients with cirrhosis and acute-on-chronic liver failure are currently underway. [41]

Assessing The Quality of RRT

There are limited data on what constitutes 'adequate' dialysis in terms of solute and fluid homeostasis and circuit function. [10] Although it is plausible that better control of uraemic solutes and volume status may translate into better survival, no randomised controlled trials have compared specific targets of urea concentration. Therefore an appropriate target urea might be 15–25 mmol/L, with a protein intake of around 1.0 g/kg/day. The aim of volume management should be to achieve euvolaemia, noting that aggressive fluid removal may delay renal recovery and increase mortality.[42] Circuit life >24 hours should be targeted and issues with circuit mechanics (e.g. pressure alarms) should be addressed immediately.

Drug Prescription During Dialytic Therapy

AKI and RRT profoundly affect drug clearance. A comprehensive description of changes in drug dosage according to the technique of RRT, residual creatinine clearance and other determinants of pharmacodynamics is beyond the scope of this chapter and can be found in specialist texts.[43] Table 56.3 provides general guidelines for the prescription of drugs commonly used in the ICU. Recent studies have shown that dosages of antibiotics remain highly variable and empirical and that their clearance with the RRT technique is highly variable, making it necessary for dosage decisions to be based on pharmacokinetic principles and an understanding of the principles of RRT removal and measurement of drug levels, where available.[44]

Table 56.3

Drug dosage during dialytic therapy [a]

DRUG	CRRT	IHD
Aminoglycosides	Normal dose q. 36 h	50% normal dose q. 48 h-2/3 re-dose after IHD
Cefotaxime or ceftazidime	1 g q. 8–12 h	1 g q. 12–24 h after IHD
Imipenem	500 mg q. 8 h	250 mg q. 8 h and after IHD
Meropenem	500 mg q. 8 h	250 mg q. 8 h and after IHD
Metronidazole	500 mg q. 8 h	250 mg q. 8 h and after IHD
Co-trimoxazole	Normal dose q. 18 h	Normal dose q. 24 h after IHD
Amoxycillin	500 mg q. 8 h	500 mg daily and after IHD
Vancomycin	1 g q. 24 h	1 g q. 96–120 h
Piperacillin	3–4 g q. 6 h	3–4 g q. 8 h and after IHD
Ticarcillin	1–2 g q. 8 h	1–2 g q. 12 h and after IHD
Ciprofloxacin	200 mg q. 12 h	200 mg q. 24 h and after IHD
Fluconazole	200 mg q. 24 h	200 mg q. 48 h and after IHD
Acyclovir	3.5 mg/kg q. 24 h	2.5 mg/kg/d and after IHD
Gancyclovir	5 mg/kg/d	5 mg/kg/48 h and after IHD
Amphotericin B	Normal dose	Normal dose
Liposomal amphotericin	Normal dose	Normal dose

DRUG	CRRT	IHD
Ceftriaxone	Normal dose	Normal dose
Erythromycin	Normal dose	Normal dose
Milrinone	Titrate to effect	Titrate to effect
Amrinone	Titrate to effect	Titrate to effect
Catecholamines	Titrate to effect	Titrate to effect
Ampicillin	500 mg q 8 hourly	500 mg daily and after IHD

[a] The above values represent approximations and should be used as a general guide only. Critically ill patients have markedly abnormal volumes of distribution for these agents which will affect dosage. CRRT is conducted at variable levels of intensity in different units also requiring adjustment. The values reported here relate to CVVH at 2 L/h of ultrafiltration. Vancomycin is poorly removed by CVVHD. IHD may also differ from unit to unit. The values reported here relate to standard IHD with low-flux membranes for 3–4 hours every second day.

D , day; *h* : hours; *q* : frequency.

Areas of Ongoing Controversy and Clinical Research

The areas of ongoing controversy and clinical research priority in RRT relate to volume management. An evolving body of evidence suggests that achieving negative fluid balance could be beneficial to patients with AKI. [45] This is supported by data suggesting that moderate-intensity fluid removal by CRRT is superior to negligible fluid removal by CRRT (>1 mL/kg/h vs. <1 mL/kg/h). [46] However, aggressive fluid removal (>1.75 mL/kg/h) also appears to be harmful and may delay renal recovery. [46] Comparing volume management practices is the subject of upcoming randomised controlled trials. It is hoped that their findings will guide the appropriate intensity of fluid removal, complementing the literature on the intensity of solute removal.

Summary

The field of RRT has undergone remarkable changes over the last 10 years and is continuing to evolve rapidly. Technology is being improved to facilitate clinical application and new areas of research are developing. In income-rich countries, CRRT is now firmly established throughout the world as the most used form of RRT for AKI in the ICU. There are no data to support the preferential use of any CRRT modality (CVVH, CVVHD and CVVHDF) over another. Two large, randomised trials have defined the optimal dose of CRRT in ICU patients as approximately 25 mL/kg/h of effluent generation. There is no benefit to early initiation of RRT in critically ill patients with AKI. The use of novel membranes and sorbents is being explored in sepsis management and liver support. Volume management is a major ongoing research priority. The intensivist needs to keep abreast of this rapidly changing field to ensure the delivery of high-quality, evidence-based care.

Acid-base disorders and hyperlactataemia

David Story, Thomas J. Morgan and David J. Cooper

Acid-base disorders are very common among critical care patients. The key diagnostic variables are pH, the partial pressure of carbon dioxide, bicarbonate and base excess. Analysis centres on looking for change and deciding if changes are related to changes in respiratory and/or metabolic (non-respiratory) physiology. Lactate is a vital consideration in disease and caries diagnostic and prognostic implications. Treatment of acid-base disorders is primarily treating the underlying disease, but patients may require organ and pharmacological support to minimise adverse effects of acid-base disorders and prevent severe acidaemia which often portends a negative outcome.

The endpoint of acid-base physiology and disorders [1] is the concentration of hydrogen ions in body fluids, notably intracellular fluids. Changes in hydrogen ion concentration can change the structure and function of proteins which are formed from amino acids that reversibly bind with hydrogen ions. Clinical chemistry measures plasma acid-status which is assumed to indicate intracellular changes. Unfortunately, rather than routinely using hydrogen ion concentration clinical chemistry reports the pH, which is the negative log base 10 of the hydrogen ion concentration. A hydrogen ion reference range for plasma of 35 to 45 nanomol/L with a midpoint value of 40 nanomol/L is equivalent to a pH reference range of 7.35 to 7.45 (no units) with a midpoint of 7.40. Therefore the pH has an inverse curvilinear relationship with the hydrogen ion concentration. Acidosis is a *process* that decreases pH while acidaemia is simply a *blood pH* , of less than 7.35. Conversely, alkalosis is a process that increases pH and alkalaemia is a blood pH greater than 7.45.

However, neither acidosis nor alkalosis is necessarily pathological, as they can be physiological compensations for other disorders, or can reflect exuberant therapies.

Assessing acid-base status centres on looking for change. [1, 2] A simplistic but pragmatic assumption is that there is an ideal physiological point in arterial blood at 37°C: pH 7.40, $PaCO_2$ 40 mm Hg (5.3 kPa), bicarbonate 24 mmol/L, base excess 0 mmol/L. Changes in these variables from this point are integrated to make diagnoses. [1] While managing the underlying clinical problem is almost always central to managing most acid-base disorders, extreme changes in pH can also be life threatening in their own right, predominantly due to changes in protein structure and function. [3] In intensive care medicine, severe acidaemia (pH <7.20) is more common than severe alkalaemia. Severe acidaemia is also usually well tolerated until the pH <7.10. Exceptions are arrythmias in prone individuals (especially with hyperkalaemia), and pulmonary hypertension in others. The much-described myocardial dysfunction with acidaemia is rarely seen in patients outside extreme pre-morbid acidaemia.

Hyperlactaemia is a common metabolic disorder in critically ill patients, and clinically relevant if the blood lactate concentration is >2.0 mmol/L. [4] Indeed, repeated blood lactate measurements in intensive care patients are as important to clinicians as monitoring the noradrenaline dose in ICU shock – regardless of the cause. So, understanding the nuances of hyperlactataemia, is as important to clinicians as understanding ICU pressors. Lactate is an end product of glycolysis, a substrate for metabolism within muscle and the brain, and a signalling molecule for altering metabolic processes. Blood lactate concentrations reflect an ongoing balance between lactate production and its metabolism (liver, red cells and skeletal muscle). Thus hyperlactataemia will occur much earlier in patients with cirrhosis than in healthy post-operative patients. Acidaemia from hyperlactataemia tends to only occur at lactate levels >4 mmol/L (because less severe acidemia is usually compensated), but the adverse prognostic implications of hyperlactataemia alone are evident throughout the measurable range with or without clinical acidaemia. [5] Understanding the clinical importance of hyperlactataemia is aided by our understanding that short-duration severe hyperlactataemia and acidosis in healthy athletes during exercise are not harmful. [4] In critically ill and high-risk patients it is important to routinely and repeatedly assess lactate concentrations over time.

This chapter will predominantly use a physical chemistry approach to acid-base disorders and hyperlactataemia. This approach brings the work of physiologist Peter Stewart[2,6] to the patient bedside[7] and like most clinical physiology has many assumptions and simplifications. Compared to other approaches Stewart's work has both supporters[1,8,9] and detractors.[10]

Water

Water is both a solvent medium and an active participant in molecular acid-base transactions. At 55.5 M/L its concentration dwarfs that of all other players and can be assumed to be a constant.[2] It is useful to model water dissociation as:

$H_2O \leftrightarrow H^+ + OH^-$ as the source of hydrogen ions in body fluids in the Stewart approach.

CO_2 Production and Disposition

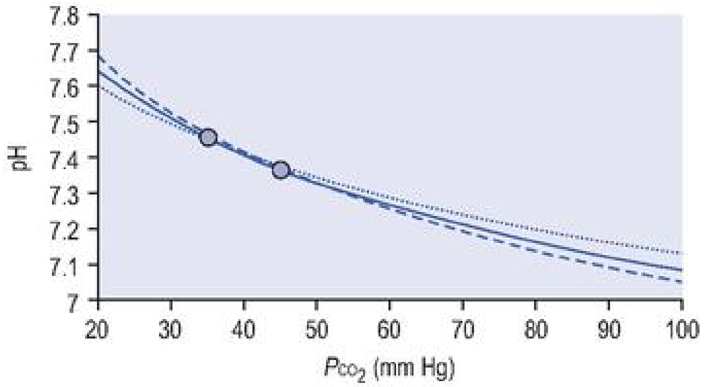
CO_2 equilibrates with different aqueous environments when transiting from its mitochondrial source to the lungs. The arterial pCO_2 and closely related alveolar pCO_2 are directly related to the metabolic CO_2 production (VCO_2) or iatrogenic CO_2 from pneumoperitoneum for laparoscopic surgery. The arterial pCO_2 is inversely related to alveolar minute ventilation (V_A). Changes in both VCO_2 and V_A affect the respiratory acid-base status, for example hyperventilation compensates for metabolic acidosis. A third factor is rebreathing which adds inspired CO_2 ($PiCO_2$) – but is usually absent.

The relationship is $PaCO_2 \propto PiCO_2 + VCO_2/V_A$, or more often $PaCO_2 \propto VCO_2/V_A$.

These relationships are at the heart of the causes and treatment of respiratory acid-base changes and respiratory compensation for metabolic acid-base changes.

The $PaCO_2$ /pH Relationship

The relationship between arterial PCO_2 ($PaCO_2$) and the pH it generates in arterial plasma is clinically important (Fig. 57.1) and is frequently disturbed in critical illness.



The line graph plots p H on the vertical axis from seven to seven point eight against partial pressure of carbon dioxide in millimetres of mercury on the horizontal axis from twenty to one hundred. Three curved lines slope downward from left to right from around seven point six to seven point seven. Three circular data points are marked along the curve, located approximately at thirty five and forty five millimetres of mercury on the horizontal axis.

FIG. 57.1 PCO_2 /pH relationships. The *solid line* shows the normal in vivo $PaCO_2$ /pH relationship. The normal $PaCO_2$ range is between the *filled circles* . To the left of the *circles* , there is an increasing acute respiratory alkalosis, and to the right an increasing acute respiratory acidosis. The interrupted curve represents the normal in vitro whole blood relationship, and the *dotted curve* is the same relationship for separated plasma. A point of commonality exists at PCO_2 =40 mm Hg.

Factors Determining the $PaCO_2$ /pH Relationship

Stewart [6] demonstrated that the pH generated by CO_2 in any body fluid can be determined from its partial pressure in combination with the following two parameters, all three being independent variables. Both pH and bicarbonate are dependent on these three ‘metabolic’ variables and the PCO_2 .

- **The strong ion difference (SID)** , which is the net charge (sum of all cations – the sum of all anions) in mEq/L of chemical entities fully ionised at pH values compatible with life. The SID of extracellular fluid (SID_{ecf}) for strong ions often measured in clinical chemistry include the cations sodium, potassium, calcium, magnesium and the anions chloride, lactate:

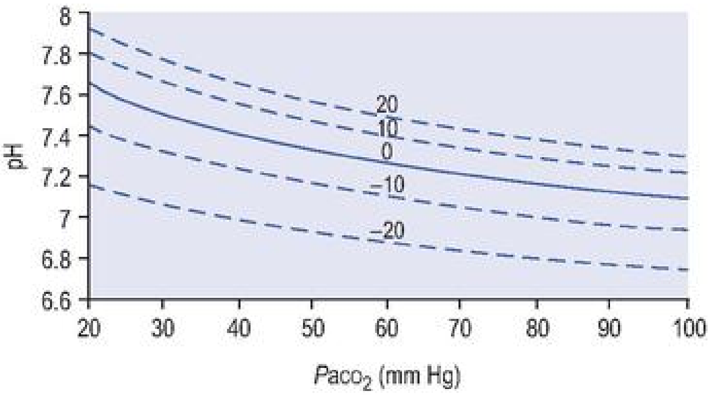
$$\begin{gathered}\text{SID, mEq/L} = [\text{Na}^+] + [\text{K}^+] + [\text{Ca}^{++}] + [\text{Mg}^{++}] - [\text{Cl}^-] \\ - [\text{L} - \text{lactate}] \\ \text{Normal plasma SID} \approx 42\text{mEq/L}\end{gathered}$$

However, the primary quantitatively and clinically important strong ions for acid-base analysis are all available in a blood gas: sodium, chloride and lactate. [7], [9]

SID, mEq/L = $[Na^+] - [Cl^-] - [\text{L-lactate}^-]$. Note that because these ions are monovalent, 1 mEq/L = 1 mmol/L, unlike divalent Ca^{++} and Mg^{++} . Normal value ≈ 34 mEq/L.

A fundamental point of the Stewart approach to clinical acid-base disorders is that as the SID decreases there is metabolic acidosis and as it increases there is metabolic alkalosis (Fig. 57.2). Acidosis in plasma from decreased SID can be caused by any of decreased sodium concentration, increased chloride concentration or increased lactate concentration.

- **The total concentration of ‘non-volatile’ weak acids (A_{tot})** . Weak acids are partly dissociated and the proportion of dissociated acid is influenced by temperature-dependent equilibrium constants. A_{tot} is the sum of the ionised and unionised weak acid fractions ($HA+A^-$). Protein, the dominant plasma A_{tot} component, has a total negative charge of 12–13 mEq/L, mostly from albumin histidine. Including inorganic phosphate and normal plasma $A_{tot} \approx 15$ mEq/L. As the A_{tot} increases there is acidosis, most often from hyperphosphataemia in kidney injury (either acute or chronic) and as A_{tot} falls there is alkalosis most commonly due to hypoalbuminaemia.



The line graph presents p H on the vertical axis from six point six to eight and partial pressure of arterial carbon dioxide in millimetres of mercury on the horizontal axis from twenty to one hundred. Five curved lines slope downward from left to right from eight to seven point two. These lines are labelled positive twenty, positive ten, zero, negative ten, and negative twenty. The zero-labelled line is centred, with positive values above and negative values below.

FIG. 57.2 $PaCO_2$/pH curve shifts and associated SBE values (mEq/L). Alterations in metabolic acid-base status shift the curve down in metabolic acidosis (SBE increasingly negative) or up in metabolic alkalosis (SBE increasingly positive).

Therefore the three factors controlling both pH and the bicarbonate concentration are the SID, A_{tot} and pCO_2.

How Acid-Base Disturbances Affect the $PaCO_2$/pH Relationship

- Acute respiratory disturbances (altered $PaCO_2$) move data points along the acute $PaCO_2$/pH curve, to the left in respiratory alkalosis and to the right in respiratory acidosis (Fig. 57.1).

- Metabolic disturbances (altered SID and/or A_{tot}) shift the entire curve, up in metabolic alkalosis and down in metabolic acidosis (Fig. 57.2).

Renal Participation in Acid-Base

Conventional descriptions of renal acid-base handling are framed on complex resorbing filtered HCO_3^-, generating new HCO_3^- and excreting hydrogen ions. The physical-chemical explanation of renal acid-base physiology is simpler, [11] centred on renal sodium and chloride handling altering the extracellular SID. Rather than explaining bicarbonate handling ammonium serves as a cation for excreting chloride without sodium increasing the plasma's SID and increases alkalaemia, while phosphate excretion reduces total weak acids in plasma.

Acid-Base Assessment: The Two 'Schools'

By convention, acid-base disorders are categorised as respiratory ($PaCO_2$) or metabolic (non-$PaCO_2$). $PaCO_2$ is the undisputed index of respiratory acid-base status. Two 'schools', Boston and Copenhagen have formed around identifying and managing metabolic acid-base disturbances. [2, 12] The Stewart approach does not undermine using these diagnostic approaches [8] and in simplified bedside forms can enhance them [7, 9] but demotes bicarbonate from being an independent mechanism and a marker of acid-base status to being a marker only.

Quantifying Metabolic Acid-Base Status

A metabolic index quantifies the 'non-PCO_2' effects on the in vivo $PaCO_2$ /plasma pH relationship. The best single index is standard base excess (BE) the Copenhagen flagship. [9] Boston school devotees estimate metabolic acid-base status indirectly by applying empiric plasma bicarbonate-based 'rules of thumb' (Table 57.1).

Table 57.1

[a] 35 mm Hg = 4.7 kPa, 45 mm Hg = 6 kPa.

Base Excess and Standard Base Excess

Base excess (BE) [9] can be defined as the amount of titratable strong ions (NaOH or HCl) in mEq/L (or mmol/L given they are monovalent ions) that returns the pH of fully oxygenated ex vivo blood to 7.40 at 37°C while PCO_2 is maintained at 40 mm Hg (5.3 kPa). However, BE, an ex vivo parameter based on blood, varies in vivo due to differences in buffering of blood connected with interstitial fluid. [12] To solve this problem Siggaard-Andersen switched to ‘plasma-diluted’ blood to better model the physiological state. [13] This is standard base excess (SBE). SBE is a stand-alone quantitative index of in vivo metabolic acid-base status, demonstrably independent of $PaCO_2$. Blood gas machines use the Van Slyke equation to calculate SBE [9] :

$$\text{SBE, mmol/L} = \left[\text{HCO}_3^-\right] - 24.8 + 16.2 \times (\text{pH} - 7.40)$$

A typical SBE reference range is −2.5 mol/L to +2.5 mmol/L.
If SBE < −2.5 mmol/L:

- There is a metabolic acidosis, either primary or as compensation for a primary chronic respiratory alkalosis.
- The SBE value is the dose of NaOH in mmol per litre of extracellular fluid (approximately 25% of body weight) required to return the downshifted $PaCO_2$/pH curve to the normal position (Fig. 57.2).

If SBE > 2.5 mmol/L:

- There is a metabolic alkalosis, either primary or as compensation for chronic respiratory acidosis.

- The SBE value is the dose of HCl per litre of extracellular fluid which would return the up-shifted curve to the normal position.

The Bicarbonate-Based Approach: The Boston ‘Rules of Thumb’

Followers of the Boston ‘school’ [12] match the plasma [HCO_3^-] against the [HCO_3^-] deemed appropriate for the measured $PaCO_2$, using ‘rules of thumb’ derived from clinical and experimental data (Table 57.1). [9] Thirty years ago Severinghaus [13] identified the relative drawbacks of the rules of thumb which included greater difficulty, lack of immediately quantifying metabolic change and calculating dose of interventions such as sodium bicarbonate. However, they can be convenient and rapid, for intensive care trainees and clinicians.

Acid-Base Disorders: Classification

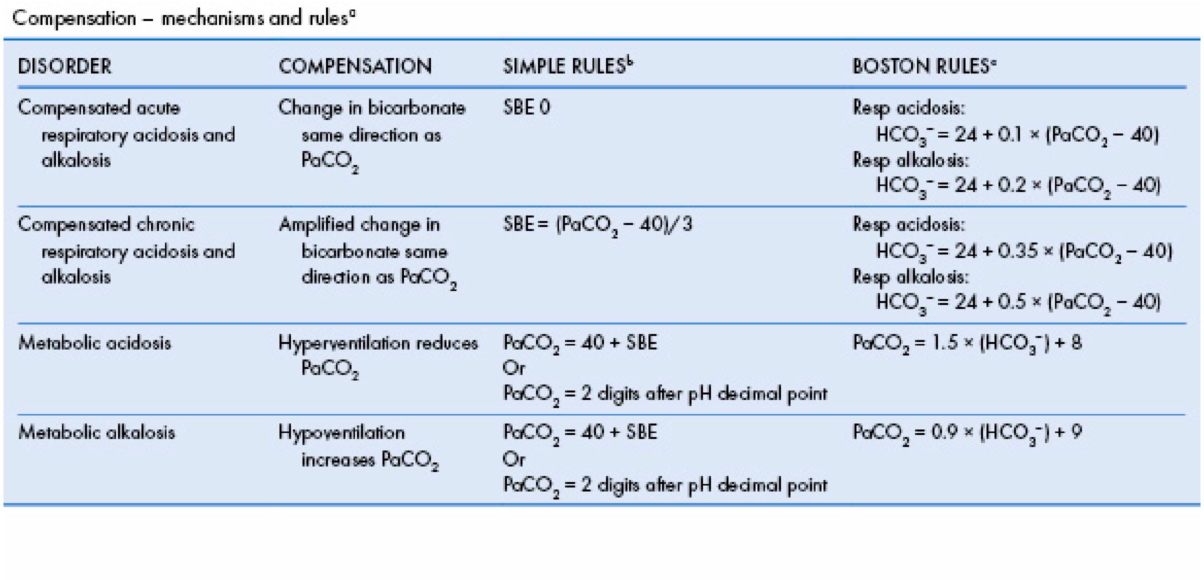
Primary Disorders

Primary disorders dictate the direction of pH disturbance. They can be respiratory ($PaCO_2$) or metabolic (non-$PaCO_2$). There can be acidaemia or alkalaemia due to respiratory or metabolic acidosis or alkalosis respectively (Table 57.1).

Compensation

Compensation is the expected physiological response to a change in respiratory or metabolic acid-base status and is a counter-response to a primary disorder, reducing the severity of the pH disturbance (Table 57.2). If expected compensation is not present, there is a mixed disorder. Therefore there are three broad possibilities: (1) no change; (2) primary disorder with compensation; and (3) mixed disorders.

Table 57.2



Compensation – mechanisms and rules[a]

DISORDER	COMPENSATION	SIMPLE RULES[b]	BOSTON RULES[c]
Compensated acute respiratory acidosis and alkalosis	Change in bicarbonate same direction as $PaCO_2$	SBE 0	Resp acidosis: $HCO_3^- = 24 + 0.1 \times (PaCO_2 - 40)$ Resp alkalosis: $HCO_3^- = 24 + 0.2 \times (PaCO_2 - 40)$
Compensated chronic respiratory acidosis and alkalosis	Amplified change in bicarbonate same direction as $PaCO_2$	$SBE = (PaCO_2 - 40)/3$	Resp acidosis: $HCO_3^- = 24 + 0.35 \times (PaCO_2 - 40)$ Resp alkalosis: $HCO_3^- = 24 + 0.5 \times (PaCO_2 - 40)$
Metabolic acidosis	Hyperventilation reduces $PaCO_2$	$PaCO_2 = 40 + SBE$ Or $PaCO_2$ = 2 digits after pH decimal point	$PaCO_2 = 1.5 \times (HCO_3^-) + 8$
Metabolic alkalosis	Hypoventilation increases $PaCO_2$	$PaCO_2 = 40 + SBE$ Or $PaCO_2$ = 2 digits after pH decimal point	$PaCO_2 = 0.9 \times (HCO_3^-) + 9$

[a] 10 mm Hg = 1.33 kPA.

[b] SBE: ± 2.5 mmol/L, $PaCO_2$ ± 5 mm Hg.

[c] HCO_3 ± 2 mmol/L, $PaCO_2$ ± 5 mm Hg.

Metabolic Compensation for Respiratory Disturbances

The kidneys respond to respiratory acid-base disturbances by altering urinary SID to reset blood SID.[11] Because SBE represents the metabolic situation if the $PaCO_2$ were 40 mm Hg (5.3 kPa), SBE will be unchanged.[9] Renal compensation is amplified in chronic respiratory changes and can return the arterial pH to the reference range (pH 7.35 to 7.45) but rarely to pH 7.40.[9] Without a clear history for the patient, metabolic compensation for chronic respiratory acidosis can be confused with primary metabolic alkalosis with both resulting in elevated plasma bicarbonate concentrations.

Respiratory Compensation for Metabolic Disturbances

Respiratory compensation for metabolic disturbances is rapid but less effective.[9] A pH of 7.40 is never regained. Feedback loops acting on central and peripheral chemoreceptors drive alveolar ventilation and $PaCO_2$ in the direction opposing the pH perturbation. A full response takes 12–24 hours, at first driven entirely by the peripheral chemoreceptors. In severe metabolic acidosis, in individuals with normal lung function, minute ventilation can increase more than 8-fold.

Lactic Acidosis

Lactate is a strong anion and increased lactate concentration without concomitant strong cations is acidifying: lactic acidosis. This occurs when the usual balance between lactate production and metabolism is disturbed. In ICU patients, reduced lactate clearance can be as important as increased production. In cardiogenic and hypovolaemic shock, hypoperfusion and tissue hypoxia lead to increased lactate production, while decreased hepatic perfusion may contribute to the decrease in lactate clearance. In septic shock, hyperlactataemia is more multifactorial and contributed to by hypoperfusion, microvascular disruption causing regional hypoperfusion and impaired mitochondrial cellular oxygen utilisation.[14] In critically ill patients, even in the absence of a lactate concentration >2.0 mmol/L, higher admission and time-weighted lactate concentrations within the normal range correlate with poorer outcomes.[15]

While there are two isomers of lactate, D and L, almost all lactic acidosis is due to L-lactate and so we refer to lactic acidosis and D-lactic acidosis. The Cohen and Woods classification[4] of lactic acidosis defines two subgroups of lactic acidosis depending on the presence (type A) or absence (type B) of tissue hypoxia (Table 57.3). Type A lactic acidosis due to tissue hypoxia is common in critically ill patients, although clinically, most patients have features of both type A and type B lactic acidosis, with increased lactate formation from tissue hypoxia, from microvascular dysfunction in sepsis, from both infused and endogenous catecholamines and from decreased lactate clearance (liver and skeletal muscle) all frequently occurring together. Type B lactic acidosis is much less common and is subdivided into three subtypes (Table 57.3). The clinical utility of this classification has been questioned. The primary management for lactic acidosis is treating the underlying cause.

Table 57.3

Classification of lactic acidosis

Type A	Shock
	Very severe hypoxaemia
	Very severe anaemia
	Carbon monoxide poisoning
Type B1 (underlying disease)	Sepsis
	Liver failure
	Thiamine deficiency
	Malignancy
	Phaeochromocytoma
	Diabetes
Type B2 (drug or toxin)	Epinephrine
	Salbutamol
	Propofol
	Nucleoside analogue reverse transcriptase inhibitor
	Ethanol
	Methanol
	Paracetamol
	Nitroprusside
	Salicylates
	Ethylene (and propylene) glycol

	Biguanides
	Fructose
	Sorbitol
	Xylitol
	Cyanide
	Isoniazid
Type B3 (rare inborn errors of metabolism)	Glucose-6-phosphatase deficiency
	Fructose-1,6 diphosphatase deficiency
	Pyruvate carboxylase deficiency
	Deficiency of enzymes of oxidative phosphorylation

The D-lactate isomer [16] is produced by some gut bacteria and in small amounts from minor metabolic pathways. The body has limited ability to eliminate D-lactate and is not detected by routine clinical lactate assays. D-lactic acidosis is rare and often associated with changes in the gut microbiome in patients with short bowel syndrome. Part of the presentation is a high anion gap (AGc) metabolic acidosis. Diagnosis is with D-lactate-specific assays. Treatment centres on managing the gut microbiome. [17]

Hyperlactaemia and Lactic Acidosis in Key ICU Patient Groups

Sepsis

In sepsis, hyperlactataemia results from both increased cellular production [18] and decreased clearance. [19] Patients are often haemodynamically unstable, and lactate production can result from inadequate oxygen delivery from hypoperfusion. During sepsis, there is also increased pyruvate production, [20] and release of lactate from lung parenchyma,[21],[22] decreased pyruvate dehydrogenase (PDH) activity[23],[24] and decreased lactate clearance.[25],[26]

Tissue hypoxia may not be the major mechanism for regional lactate production during sepsis: where hyperlactataemia is linked to the severity of the septic cellular inflammatory response and hypermetabolic state.[27],[28] Net lactate production from the hepatosplanchnic bed is uncommon in septic patients[29] and nuclear magnetic resonance spectroscopy indicates that hyperlactataemia may occur without tissue hypoxia.[30] Nevertheless, the role of hyperlactataemia as a prognostic marker during sepsis is very clear, with mortality increasing with increasing lactate concentrations.[31-33]

Brain Injury

Lactate may be an important energy *substrate* in brain metabolism.[34],[35] It is hypothesised that lactate is an alternative energy source to compensate for decreased glucose uptake in injured brain tissue.[36] Increased brain lactate as measured by cerebral microdialysis has been associated with improved survival,[37] leading to early studies of supplemental lactate to improve outcomes after traumatic brain injury.[38-40]

Lung Injury

In acute lung injury, the lung is a primary source of lactate production, with the pulmonary release of lactate directly related to the severity of lung injury.[22],[41] Major contributors to hyperlactataemia are the tissues with the most inflammation or injury. Increased lactate production by injured lung is not only secondary to anaerobic metabolism in hypoxic lung regions but also due to altered glucose metabolism and a direct effect of cytokines on pulmonary cells.[41] Both metabolic and respiratory acidosis appears to protect the lung against injury while correcting acidosis compounds lung injury.[42],[43] There is growing evidence that hypercapnic acidosis may be beneficial in lung injury,[42],[44] Clinicians now have a greater tolerance of acidosis during ARDS, and also increased reluctance to correct acidosis towards ‘normal’ values.

Asthma

Hyperlactataemia often occurs in patients with acute severe asthma, and the acidosis is attributed to fatiguing respiratory muscles, [45] inadequate oxygen delivery to the respiratory muscles to meet the elevated oxygen demand [46] and liver ischaemia. However, severe hyperlactataemia also occurs in sedated, paralysed mechanically ventilated patients who have no endogenous respiratory muscle activity. [47] Stimulation of β adrenergic receptors by β agonists, including salbutamol and adrenaline, leads to a variety of metabolic effects including increased glycogenolysis, gluconeogenesis and lipolysis [48] and is often the primary contributor to hyperlactataemia. In asthma, decreasing intravenous salbutamol infusions to less than 10 mcg/min usually leads to resolution of the acidosis. In this context, hyperlactataemia does not have any prognostic implications.

Mesenteric Ischaemia and D-Lactic Acidosis

Mesenteric ischaemia in the critically ill may have few clinical or diagnostic signs. An ischaemic bowel, however, can produce large amounts of lactate, and the presence of hyperlactataemia in the setting of acute abdominal disease is a strong indicator of mesenteric ischaemia. In addition, elevated lactate at the time of diagnosis of mesenteric ischaemia is a predictor of mortality. [49] However, although plasma lactate is a very sensitive marker (100%) for detecting acute mesenteric ischaemia, it has low specificity (42%) in the critically ill, who can have other diagnoses. A mesenteric ischaemia diagnosis is often made first at laparotomy in ICU patients.

Acid-Base ‘Scanning Tools’

Electrical Gaps

Gaps between measured cations and anions (strong and weak) can be filled with known and unknown strong anions and weak acids (Table 57.4). Accumulating anions can be injurious, [50] especially in poisonings, but apart from chloride and L-lactate are not measured routinely. Practitioners use electrical ‘gaps’ as early warning systems for unmeasured ions. However, in conditions such as sepsis and trauma the unmeasured ions may vary between patients and within patients across time and prognostic significance may vary.[50]

Table 57.4

Causes of metabolic acidosis

NORMAL AGc **DECREASED Na-Cl SID**	**RAISED AGc** **RAISE LACTATE AND/OR OTHER IONS**
Saline infusions Organic anion excretion (Glue sniffing – hippurate, benzoate) Loss of high SID enteric fluid (Small intestinal, pancreatic, biliary) Urinary to enteric diversions (High urinary SID) Renal tubular acidosis (High urinary SID) Chronic kidney disease Post hypocapnia (High urinary SID) TPN and NH_4Cl administration	L-lactate acidosis Ketoacidosis (Beta-hydroxybutyrate, acetoacetate) Acute kidney injury Chronic kidney disease (Sulphate, hippurate, other organic anions) Phosphate accumulation Ethylene glycol poisoning (Glycolate, oxalate) Methanol poisoning (Formate) Salicylate overdose (Salicylate, L-lactate, keto-anions) Pyroglutamic acidosis (Pyroglutamate) Toluene (glue sniffing) (Hippurate, benzoate) Short bowel syndrome (D-lactate)

Anion Gap (AG)

- Calculated as $([Na^+]+[K^+]) - ([Cl^-]+HCO_3^-])$
- $[K^+]$ is often omitted

- Typical reference range 3–13 mEq/L
- In health the AG is mainly the negative charge on albumin and to a lesser extent phosphate
- Simple to calculate
- Lowest sensitivity and specificity

Albumin-Corrected Anion Gap (AGc) – Preferred

- $\mathrm{AGc} = \mathrm{AG} + 0.25 \times (42 - [\mathrm{albumin}])$, assuming normal plasma $[\mathrm{albumin}] = 42$ g/L
- Corrects for albumin offsets which are very common among critical care patients [51], [52]
- Same reference range as AG
- A relatively simple ‘bedside’ calculation
- Lactate is not routinely included in the AGc calculation but can be if the measurement is available

Strong Ion Gap (SIG)

- SIG mEq/L $= [\mathrm{Na}^+] + [\mathrm{K}^+] + [\mathrm{Ca}^{++}] + [\mathrm{Mg}^{++}] - [\mathrm{Cl}^-] - [\mathrm{Lactate}] - 0.25 \times [\mathrm{albumin}] - [\mathrm{HCO}_3^-]$
- Essentially a modified AGc with a mixture of bicarbonate and Stewart approaches
- Lactate included but significance may be obscured
- Reference range notionally centred on zero but requires local calibration
- Variability is likely increased due to multiple analytes
- ‘Strong ion gap’ is a misnomer. Gap ions can be strong or weak
- Bedside calculation is less feasible

Bedside Stewart

This approach quantifies the effects of changes in principal plasma strong ions (Na, CL and lactate) and weak acids (albumin) on SBE. Residual effects are assumed to be due to unmeasured ions: strong ions, weak acids and bases.

$$
\begin{aligned}
\text{SBE mEq/L} = {} & \text{base-excess effect of sodium chloride} \\
& [\text{Na} - \text{Cl} - 35] \\
& + \text{base-excess effect of albumin } [0.25 \times (42 - \text{albumin, g/L})] \\
& + \text{base-excess effect of lactate } [1 - \text{lactate}] \\
& + \text{base-excess effect of other ions}
\end{aligned}
$$

- Na-Cl effect quantified
- Lactate is routinely assessed and effect quantified
- Acid-base effects of albumin changes quantified
- The SBE effect of other ions is solved by subtracting the Na-Cl, Albumin and lactate SBE effects from the overall SBE. Assuming albumin is normal will probably underestimate the effect of unmeasured ions similar to using AG instead of AGc
- Related to the AGc but quantifies the metabolic effect of unmeasured ions

Practical Considerations

The Diagnostic Sequence

After taking a history and examining the patient, the next step is assenting an arterial blood gas. [9] Venous samples have limitations but are an alternative when arterial samples are not readily available, but the effects of venous sampling sites need to be considered. [53]

What Is the Primary Process?

- The primary process (Table 57.1) determines the direction of pH change.

- Look first at the $PaCO_2$ and then at the pH it generates (Table 57.1 , Fig. 57.1).
- If both are normal, there is often no abnormality, but combined metabolic alkalosis and acidosis are still possible often due to hypoalbuminaemia [51] this can be identified through bedside Stewart and AGc or relative hypochloraemia which the AGc will miss but Bedside Stewart is likely to detect.
- If either or both are abnormal, check whether the direction of pH change is appropriate for the $PaCO_2$:
  - Appropriate: Primary respiratory disorder.
  - Inappropriate: Primary metabolic disorder.
- Nine possible combinations of $PaCO_2$ and pH (Table 57.1) indicate specific acute, chronic or mixed primary processes.
- An abnormal $PaCO_2$ plus a normal pH means either:
  - Two opposing primary acid-base disorders, one respiratory and one metabolic.
  - A chronic respiratory disturbance with metabolic compensation.
- A ‘normal’ $PaCO_2$ combined with an abnormal pH always represents two primary acid-base disturbances (Tables 57.1 and 57.2).

Is There Compensation?

- Metabolic acidosis: compensation = $PaCO_2$ <35 mm Hg (4.6 kPa)
- Metabolic alkalosis: compensation = $PaCO_2$ >45 mm Hg (6.0 kPa)
- Acute respiratory alkalosis: compensation = SBE 0 mEq/L
- Acute respiratory acidosis: compensation = SBE 0 mEq/L
- Chronic respiratory acidosis: compensation = SBE >2.5 mmol/L
- Chronic respiratory alkalosis: compensation = SBE < −2.5 mmol/L

Is Compensation Appropriate?

- In the presence of a primary respiratory or metabolic disorder, secondary compensation in the other system resets what is ‘normal’. For example, for a primary metabolic acidosis (SBE −6.5 mmol/L) a

PaCO$_2$ of 42 mm Hg (5.6 kPa) becomes a mixed metabolic acidosis and respiratory acidosis while a PaCO$_2$ of 34 mm Hg (4.5 kPa) becomes the expected PaCO$_2$.

- Apply the simple Base-excess rules or the more complex Boston ‘rules of thumb’ (Table 57.2)
  - the pH is often normal in fully compensated respiratory acid-base disturbances (can take days).
  - the pH is never normal in appropriately compensated metabolic acid-base disturbances.
- Inappropriate, evolving or inadequate respiratory compensation (including from mechanical ventilation) is a mixed disorder.[9]

If Metabolic Acidosis Is Present, How Severe Is It?

- Mild: SBE −4 mEq/L to −9 mEq/L
- Moderate: SBE −10 mEq/L to −14 mEq/L
- Severe: SBE < −14 mEq/L

If Metabolic Alkalosis Is Present, How Severe Is It?

- Mild: SBE +4 mEq/L to +9 mEq/L
- Moderate: SBE +10 mEq/L to +14 mEq/L
- Severe: SBE > +14 mEq/L

Check the Lactate

Are There Unmeasured Ions?

- Look for unmeasured anions using Bedside Stewart or AGc even when pH is in the reference range or alkalaemic. AGc can also be adjusted for lactate by adding [Lactate] − 1 to the AGc.

- If AGc is low or negative, suspect laboratory error, but consider lithium intoxication, IgG myeloma and others (Table 57.2).

If Other Anions Are Present, What Are They?

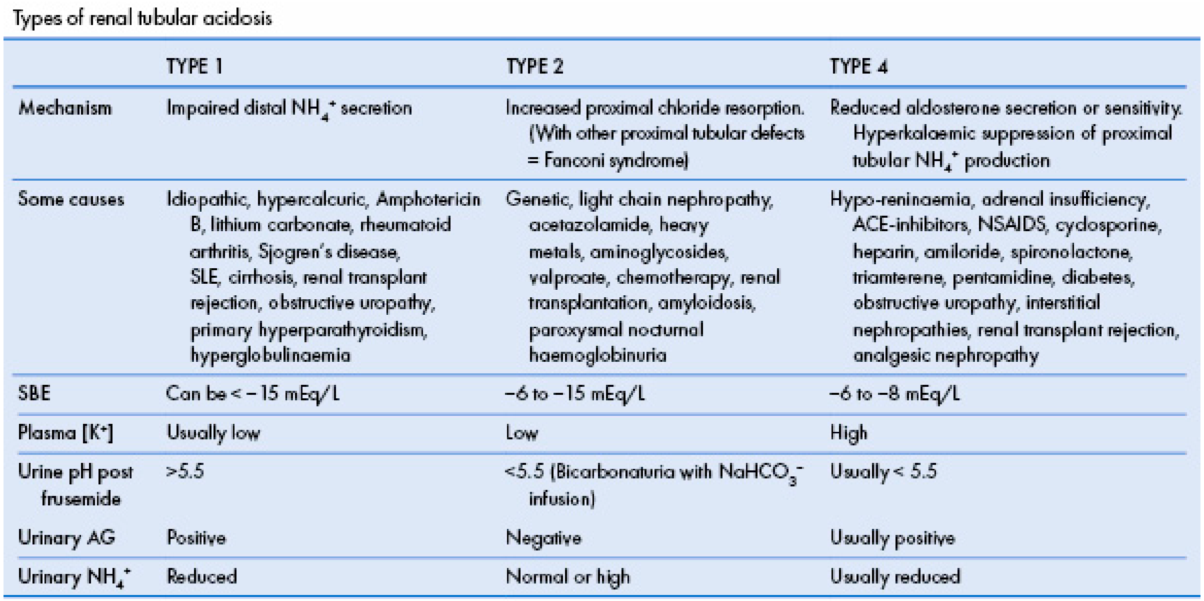
- Lactate should be routinely assessed. Other increasingly common cause are keto-anions. There are several others (Table 57.4)
- If no obvious cause, a coincident raised osmolal gap suggests methanol (unmeasured anion formate) or ethylene glycol toxicity (unmeasured anions glycolate and oxalate).
- If still no obvious cause, perform specific assays (salicylate, pyroglutamate, urinary organic anions and phosphate).
- But, it is well recognised that there are known unknown and unknown unknown pathological anions in ICU clinical chemistry.[5,50,54]

Clinical Acid-Base Disorders

Metabolic Acidosis

There are many causes of metabolic acidosis (Tables 57.4 and 57.5). While there are other options,[55,56] the Bedside Stewart approach can help identify and quantify the causes of metabolic acidosis[7] : the Na-Cl SID, lactate and unmeasured ions. Hyperchloraemia does not always lead to a normal AGc acidosis because [Cl$^-$] is only important relative to [Na$^+$], it is the difference between these strong ions that counts, and the major factor is SID$_{ecf}$.

Table 57.5



Types of renal tubular acidosis

	TYPE 1	TYPE 2	TYPE 4
Mechanism	Impaired distal NH_4^+ secretion	Increased proximal chloride resorption. (With other proximal tubular defects = Fanconi syndrome)	Reduced aldosterone secretion or sensitivity. Hyperkalaemic suppression of proximal tubular NH_4^+ production
Some causes	Idiopathic, hypercalcuric, Amphotericin B, lithium carbonate, rheumatoid arthritis, Sjogren's disease, SLE, cirrhosis, renal transplant rejection, obstructive uropathy, primary hyperparathyroidism, hypergl obulinaemia	Genetic, light chain nephropathy, acetazolamide, heavy metals, aminoglycosides, valproate, chemotherapy, renal transplantation, amyloidosis, paroxysmal nocturnal haemoglobinuria	Hypo-reninaemia, adrenal insufficiency, ACE-inhibitors, NSAIDS, cyclosporine, heparin, amiloride, spironolactone, triamterene, pentamidine, diabetes, obstructive uropathy, interstitial nephropathies, renal transplant rejection, analgesic nephropathy
SBE	Can be < -15 mEq/L	-6 to -15 mEq/L	-6 to -8 mEq/L
Plasma $[K^+]$	Usually low	Low	High
Urine pH post frusemide	>5.5	<5.5 (Bicarbonaturia with $NaHCO_3^-$ infusion)	Usually < 5.5
Urinary AG	Positive	Negative	Usually positive
Urinary NH_4^+	Reduced	Normal or high	Usually reduced

Clinical Features

The adverse effects of acidaemia (Table 57.6) are more evident at low pH (<7.2) where there is a greater change in protein structure and function. In addition to iatrogenic Na-Cl acidosis 0.9%, saline-induced hyperchloraemia may cause impairment of renal blood flow and renal impairment. [57] Other anions can have specific poisoning syndromes [55] in addition to metabolic acidosis.

Table 57.6

Adverse effects of metabolic acidosis

Reduced myocardial contractility, tachy- and brady-dysrhythmias, systemic arteriolar, venoconstriction, centralisation of blood volume
Pulmonary vasoconstriction, hyperventilation, respiratory muscle failure
Reduced splanchnic and renal blood flow
Increased metabolic rate, catabolism, reduced ATP synthesis, reduced 2,3-DPG synthesis
Confusion, drowsiness
Increased inducible nitric oxide synthetase expression, pro-inflammatory cytokine release
Hyperglycaemia, hyperkalaemia
Cell membrane pump dysfunction
Bone loss, muscle wasting

Renal Tubular Acidosis (RTA)

In RTA, the urinary SID setting is high relative to the SID_{ECF}, with an inadequate nadir following an acid load. The disturbance is in renal tubular Cl^- handling, either from reduced ammonia production (Types 1 and 4) or excessive chloride resorption (Type 2). [58] Causes are legion (Table 57.5). [55]

In the presence of metabolic acidosis, if urine pH is acidic and SID is low or negative, a compensatory response of the kidney is present; if the opposite holds true, the kidney is not able to compensate and this is associated with a worse prognosis. [58, 59]

Management of Metabolic Acidosis

Management is directed at the underlying cause. During mechanical ventilation, hyperventilation is required to match the normal compensating respiratory response, and conversely, mechanical hypoventilation can precipitate extreme acidosis, hyperkalaemia and cardiac arrhythmia.

Alkalinising Agents

Alkalinising agents increase the pH at any given PCO_2. In other words, they increase the SBE (Fig. 57.2). Administration of alkalinising agents is not indicated in hyperlactataemia and other organic acidoses. The Surviving Sepsis guidelines (2016) strongly recommended against the use of bicarbonate when treating hypoperfusion-induced lactic acidaemia in patients with a pH ≥7.15, [60] while others have recommended a lower target pH of 7.00 or less. [61]

However, it can be appropriate to infuse $NaHCO_3$ in: severe acidaemia with acute kidney injury, severe normal AGc acidosis, severe hyperkalaemia, TCA overdose and other-ion poisonings, pulmonary hypertension with right heart dysfunction (e.g. lung transplants) and severe ischaemic heart disease patients where the risk of major arrhythmias is high.

An ongoing ANZICS-CTG and multinational randomised NHMRC trial is testing whether bicarbonate infusions for ICU patients with early acute renal failure and acidosis can improve long-term renal outcomes. [62] The findings may change clinical practice in many ICU patients, as many have renal dysfunction.

Sodium bicarbonate ($NaHCO_3$) preparations increase SBE by increasing SID. A $NaHCO_3$ dose of 1 mmol/kg increases SBE by approximately 3 mEq/L. The active agent is sodium, not bicarbonate and so the solution is better described as sodium with CO_2. However, the high CO_2 content in 8.4% (1000 mmol/L) $NaHCO_3$ can create the expected problem of intracellular respiratory acidosis which can be reduced through increasing minute ventilation when mechanically ventilated and through slow administration over at least 30 to 60 minutes. Slow administration also helps prevent intravascular volume overload from the hypertonic bicarbonate solution.

Sodium Lactate

Sodium lactate (0.167M, pH 6.9) is an alternative, provided lactate metabolism is efficient. Removing lactate from the ECF will increase the SID. Further, evidence for half molar lactate may be a valuable resuscitation fluid, and treatment in specific circumstances assuming that that glucose metabolism is impaired in the injured brain and heart and that lactate provides a preferential or opportunistic energy substrate for injured tissues. [63]

Metabolic Alkalosis

Metabolic alkalosis has been described as the most common acid-base disturbance in ICU patients. It is often part of a 'mixed' disorder.

Causes (Table 57.7)

Metabolic alkalosis can be precipitated by:

1. Low urinary SID (e.g. diuretics)
2. Loss of low SID enteric fluid (e.g. small gut fistulae)
3. Gain of high SID fluid (e.g. $NaHCO_3$ administration)

Table 57.7

Metabolic alkalosis – causes

LOW URINARY SID	ENTERIC LOSSES OF LOW SID FLUID	GAIN OF HIGH SID FLUID
Loop or thiazide diuretics Post-hypercapnia Corticosteroids Cushing's syndrome Primary mineralocorticoid excess Carbenoxolone Glycyrrhetinic acid (licorice) Hypercalcaemia Milk alkali syndrome Magnesium deficiency Bartter and Gitelman syndromes	Gastric contents (pyloric stenosis, vomiting, gastric outlet obstruction, nasogastric suction) Villous adenoma Laxative abuse	$NaHCO_3$ administration Sodium citrate (plasma exchange, stored blood) Renal replacement fluids with high SID (>35 mEq/L) Milk alkali syndrome

Clinical Features

A high plasma pH (>7.55) has a number of adverse effects (Table 57.8). Mortality escalates as the pH rises above 7.55, although causation versus association is unclear.

Table 57.8

Severe metabolic alkalosis - multi-system effects

Central nervous system	
	Vasospasm
	Seizures
	Confusion, drowsiness
Neuromuscular	
	Weakness, tetany, muscle cramps
Cardiovascular	
	Arrhythmias – supraventricular and ventricular
	Decreased contractility
Respiratory	
	Decreased alveolar ventilation
	Atelectasis, hypoxaemia
Metabolic	
	Hyperlactataemia
	Low [Pi], $[Ca^{++}]$, $[Mg^{++}]$ and $[K^{+}]$
Haemoglobin-oxygen affinity	
	Initially increased (until counteracted by increased 2,3-DPG)

Table 57.9

Some causes of respiratory acidosis

MECHANISM/AFFECTED SITE	ACUTE	CHRONIC
Respiratory centre suppression	Sedative and narcotic drugs, CNS injury, CNS infection, brain stem vasculitis or infarction	Obesity hypoventilation syndrome
Airway obstruction	Inhalational injury, Ludwig’s angina, laryngeal trauma Airway oedema, foreign body	Obstructive sleep apnoea, vocal cord paresis, sub-glottic and tracheal stenosis
Mechanical ventilation	Decreased VA (permissive hypercapnia) Rebreathing	Chronic assisted ventilation
Neural/neuromuscular	Spinal cord injury, Guillain-Barre syndrome, myaesthenia gravis, muscle relaxants, envenomation, acute poliomyelitis, critical illness myoneuropathy, acquired brain injury	Phrenic nerve damage, paraneoplastic syndromes, post-polio syndrome
Increased CO_2 output	Sepsis	

MECHANISM/AFFECTED SITE	ACUTE	CHRONIC
	Hypermetabolism Bicarbonate therapy CO_2 pneumoperitoneum for surgery	
Muscle	Myopathy, low [K^+], high [Mg^+], low [Pi], diaphragmatic injury, shock	Muscular dystrophies, motor neuron disease
Decreased chest wall compliance	Abdominal distension, burns, pneumothorax, large pleural effusions	Obesity, kyphoscoliosis, ankylosing spondylitis
Loss of chest wall integrity/geometry	Flail segment Ruptured diaphragm	Thoracoplasty
Increased small airways resistance	Asthma, bronchiolitis	Chronic obstructive pulmonary disease
Deceased lung compliance	Acute lung injury, pneumonia, pulmonary oedema, vasculitis and haemorrhage	Pulmonary fibrosis

Treatment

Remove the cause. Other measures to facilitate reducing the SID (acidifying, Fig. 57.2) of the ECF include:

- Assessment of volume status, supplemented as needed by urinary chloride analysis
- Correct extracellular depletion with saline or low SID colloids
- KCl (SID zero) to correct potassium depletion
- Acetazolamide to increase urinary SID is sometimes used in COPD patients to stimulate respiratory drive but has limited efficacy
- Chloride administration via slow HCl infusion through a central venous catheter
- Renal replacement therapy

As with metabolic acidosis, care is required when instituting mechanical ventilation to avoid severe alkalaemia from mixed alkalosis.

Respiratory Acidosis

Causes

The risk is increased when CO_2 production is high and/or when ventilation is inefficient (reduced consciousness, large alveolar or apparatus dead space, respiratory muscle disadvantage due to hyper-inflation or increased work of breathing) (Table 57.9).

Clinical Features

These include:

- The effects of acidaemia (Table 57.6)
- Asterixis, confusion, drowsiness, fitting and raised intracranial pressure
- Reduced renal perfusion, glomerular filtration rate and urine output due to activation of sympatho-adrenal and renin-angiotensin systems

Treatment

Management is directed at the underlying cause. Mechanical ventilation, either non-invasive or invasive, may be required.

Respiratory Alkalosis

Causes

The causes all lead to hyperventilation (Table 57.10)

Table 57.10

Conditions predisposing to respiratory alkalosis

ACUTE	CHRONIC
Hypoxaemia Hepatic failure Sepsis Asthma Pulmonary embolism Pneumonia, acute lung injury CNS disorders – stroke, infection, trauma Drugs – salicylates, selective serotonin reuptake inhibitors Opiate and benzodiazepine withdrawal Mechanical hyperventilation Pain, anxiety, psychosis	Pregnancy High altitude Chronic lung disease Neurotrauma Chronic liver dysfunction

Clinical Features

The multi-system effects of alkalaemia apply (Table 57.8), plus the complications of reactive hypoventilation.

Treatment

Management should be directed towards the underlying cause.

Fluid and electrolyte therapy

Anthony Delaney, Priya Nair, Naomi E. Hammond, Simon Finfer and John Myburgh

The management of patients' fluid and electrolyte status requires an understanding of body fluid compartments as well as an understanding of water and electrolyte metabolism. These principles will be considered along with the commonly encountered fluid and electrolyte disturbances. Recent evidence for the use of fluid therapy in a number of common clinical scenarios will also be presented.

Fluid Compartments (Table 58.1 ; Fig. 58.1)

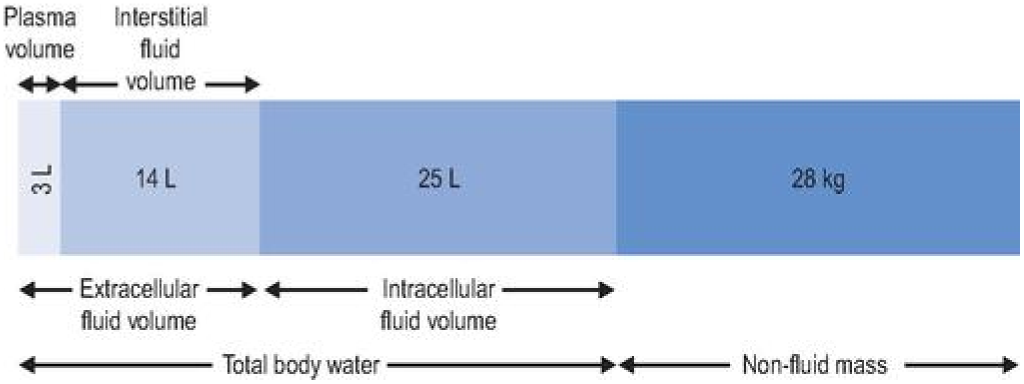
Total Body Water

In humans, water contributes approximately 60% of body weight, with organs varying in water content (Table 58.2). The variation of the percentage of total body weight as water, between individuals, is largely governed by the amount of adipose tissue. The average water content as a percentage of total body weight is 60% for males and 50% for females. Total body water as a percentage of total body weight decreases with age, due to a progressive loss of muscle mass, causing bone and connective tissue to assume a greater percentage of total body weight (Table 58.3).[1-3]

Table 58.1

Body fluid compartments

FLUID COMPARTMENT	VOLUME (mL/kg)	% TOTAL BODY WEIGHT
Plasma volume	45	4.5
Blood volume	75	7.5
Interstitial volume	200	20
Extracellular fluid volume	250	25
Intracellular fluid volume	350	35
Total body fluid volume	600	60



Plasma volume
Interstitial fluid volume
3 L
14 L
25 L
28 kg
Extracellular fluid volume
Intracellular fluid volume
Total body water
Non-fluid mass

The diagram illustrates the distribution of body fluids and non-fluid mass in a horizontal bar. From left to right, a narrow section labelled Plasma volume shows 3 litres. Next, a larger section labelled Interstitial fluid volume represents 14 litres. Together, they form the Extracellular fluid volume. Adjacent is a section labelled Intracellular fluid volume, marked as 25 litres. These combined areas represent Total body water. The final section, labelled Non-fluid mass, is marked as 28 kilograms.

FIG. 58.1 Body fluid compartments.

Table 58.2

Water content of various tissues

TISSUE	% WATER CONTENT
Brain	84
Kidney	83
Skeletal muscle	76
Skin	72
Liver	68
Bone	22
Adipose tissue	10

Table 58.3

Water content as a percentage of total body weight

AGE (YEARS)	MALES (%)	FEMALES (%)
10–15	60	57
15–40	60	50
40–60	55	47
>60	50	45

Total body water is commonly divided into two volumes: the extracellular fluid (ECF) volume and the intracellular fluid (ICF) volume. [2] Sodium balance regulates the ECF volume, whereas water balance regulates the ICF volume. Sodium excretion is normally regulated by various hormonal and physical ECF volume sensors, whereas water balance is normally regulated by hypothalamic osmolar sensors. [4]

Extracellular Fluid

ECF is defined as all body water external to the cell and is commonly subdivided into plasma and interstitial fluid volumes. The ECF is normally 40% of total body water and 25% of total body weight. With acute or chronic illness, ICF volume is reduced, and ECF volume is increased and may even exceed the ICF volume.

Intracellular Fluid

ICF is defined as all the body water within cells and, unlike the ECF compartment, is an inhomogeneous, multicompartmental entity, with different pH and ionic compositions depending upon the organ or tissue being considered. The ICF volume is often determined by inference from the difference in measurements of the total body water and ECF spaces. This estimation suffers from the inaccuracies inherent in both ECF and total body water measurements. In general, the ICF is considered to be 60% of total body water and 35% of total body weight.

Transcellular Fluid

Fluids in this compartment have a common characteristic of being formed by the transport activity of cells. The fluid is extracellular in nature and will be considered part of the interstitial volume. It may vary from 1 L to 10 L, with larger volumes occurring in diseased states (e.g. bowel obstruction or cirrhosis with ascites), and is formed at the expense of the remaining interstitial and plasma volumes.

Water Metabolism

Water balance is maintained by altering the intake and excretion of water. In the healthy state, intake is controlled by thirst. Excretion is controlled by the renal action of antidiuretic hormone (ADH). In health, plasma osmolalities of about 280 mOsm/kg suppress plasma ADH to concentrations low enough to permit maximum urinary dilution. [5] Above this value, an increase in ECF tonicity of about 1%–2% or a decrease in total body water of 1–2 L causes the posterior pituitary to release ADH, which acts upon the distal nephron to increase water reabsorption. Maximum plasma ADH concentrations are reached at an osmolality of 295 mOsm/kg.[5] The osmotic stimulation also changes thirst sensation and, in the conscious ambulant individual, initiates water repletion (drinking), which is more important in preventing dehydration than ADH secretion and action. Thus, in health, the upper limit of the body osmolality (and therefore serum sodium) is determined by the osmotic threshold for thirst, whereas the lower limit is determined by the osmotic threshold for ADH release.[6]

Increase in osmolality caused by permeant solutes (e.g. urea) does not stimulate ADH release. ADH may also be released in response to hypovolaemia and hypotension, via the stimulation of low- and high-pressure baroreceptors. ADH release is extremely marked when more than 30% of the intravascular volume is lost. ADH may also be stimulated by pain and nausea, which are thought to act through the baroreceptor pathways.[4] ADH release may also be stimulated by a variety of pharmacological agents (Table 58.4). Renal response to ADH depends upon an intact distal nephron and collecting duct, and a hypertonic medullary interstitium. The capacity to conserve or excrete water also depends upon the osmolar load presented to the distal nephron.[4]

Table 58.4

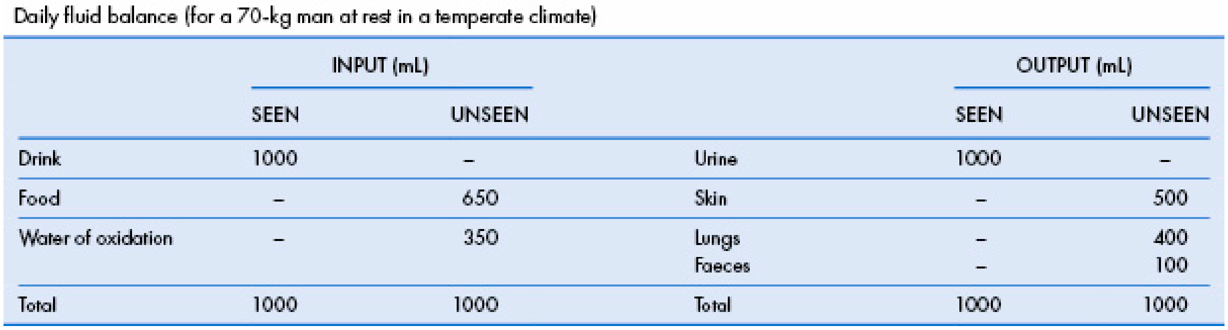
Drugs affecting antidiuretic hormone secretion

STIMULATE	INHIBIT
Nicotine	Ethanol
Opiate analgesics	Opiate antagonists
Vincristine	Phenytoin
Barbiturates	
Cyclophosphamide	
Chlorpropamide	
Clofibrate	
Carbamazepine	
Amitriptyline	

Water Requirements

Water is needed to eliminate the daily solute load, and to replace daily insensible fluid loss (Table 58.5). With a normal daily excretion of 600 mOsm solute, maximal and minimal secretions of ADH will cause urine osmolality to vary from 1200 to 30 mOsm/kg, respectively, and the urine output to vary from 500 mL to 20 L/day, respectively. Skin and lung water losses vary and may range from 500 mL to 8 L/day depending on physical activity, ambient temperature and humidity.

Table 58.5



Daily fluid balance (for a 70-kg man at rest in a temperate climate)

	INPUT (mL)			OUTPUT (mL)	
	SEEN	UNSEEN		SEEN	UNSEEN
Drink	1000	–	Urine	1000	–
Food	–	650	Skin	–	500
Water of oxidation	–	350	Lungs	–	400
			Faeces	–	100
Total	1000	1000	Total	1000	1000

Disorders of Osmolality

Tonicity

Osmolality is a measure of the number of osmoles per kilogram (Osm/kg) of water. Tonicity is a measure of the effective osmotic pressure gradient when two fluid compartments are separated by a semi-permeable membrane. Tonicity is influenced only by solutes that cannot cross the membrane. The osmolality of the ECF is due largely to sodium salts. Clinical effects of hyperosmolality, due to excess solute, depend upon whether the solute distributes evenly throughout the total body water (e.g. permeant solutes of alcohol or urea) or distributes in the ECF only (e.g. impermeant solutes of mannitol or glucose). With impermeant solutes, hyperosmolality is associated with a shift of fluid from the ICF to the ECF compartment. Hyperosmolality due to increased impermeant solutes is known as hypertonicity. This condition may also be associated with a reduction in the serum sodium concentration (see below).

Water Excess

In a 70 kg human, for every 1 L of excess pure water, ECF increases by 400 mL and ICF increases by 600 mL, on average. The osmolality also decreases by 6–7 mOsm/kg and the serum sodium falls by 3.0–3.5 mmol/L.

Water Deficiency

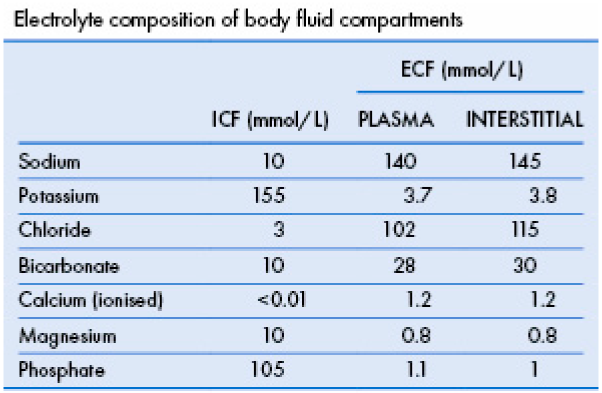
In a 70 kg human, for every 1 L of pure water loss, approximately 600 mL is lost from the ICF and 400 mL from the ECF. The osmolality also increases by 7–8 mOsm/kg and the serum sodium rises by 3.5–4.0 mmol/L.

Electrolytes

Chemical compounds in solution may either:

- remain intact (i.e. undissociated), in which case they are called non-electrolytes (e.g. glucose and urea)
- dissociate to form ions, in which case they are called electrolytes. Ions carry an electrical charge (e.g. Na^+ and Cl^-). Ions with a positive charge are attracted to a negative electrode or cathode, and hence are called 'cations'. Conversely, ions with a negative charge travel towards a positive electrode or anode and are called 'anions'. Each body water compartment contains electrolytes with different compositions and concentrations (Table 58.6).

Table 58.6



Electrolyte composition of body fluid compartments

	ICF (mmol/L)	ECF (mmol/L)	
		PLASMA	INTERSTITIAL
Sodium	10	140	145
Potassium	155	3.7	3.8
Chloride	3	102	115
Bicarbonate	10	28	30
Calcium (ionised)	<0.01	1.2	1.2
Magnesium	10	0.8	0.8
Phosphate	105	1.1	1

ECF , Extracellular fluid; *ICF* , intracellular fluid.

Sodium

Sodium is the principal cation of the ECF and accounts for 86% of the ECF osmolality. In a 70 kg human, total body sodium content is approximately 4000 mmol (58 mmol/kg) and is divided into a number of compartments (Table 58.7). Normal ECF concentration of sodium varies between 134 and 146 mmol/L. The intracellular sodium concentration varies between different tissues and normally ranges from 3 to 20 mmol/L.

Table 58.7

The sodium compartments in a 70-kg man

	TOTAL (mmol)	(mmol/kg)
Total body sodium	4000	58
Non-exchangeable bone sodium	1200	17
Exchangeable sodium	2800	40
Intracellular sodium	250	3
Extracellular sodium	2400	35
Exchangeable bone sodium	150	2

Daily intake of sodium varies widely, with urinary losses ranging from less than 1 to greater than 240 mmol/day. [7] Sodium balance is influenced by renal hormonal and ECF physical characteristics. The complete renal adjustment to an altered sodium load usually requires 3–4 days before the balance is restored.

Hyponatraemia

Hyponatraemia is defined as serum sodium less than 135 mmol/L and may be classified as isotonic, hypertonic or hypotonic, depending upon the measured serum osmolality (Box 58.1).

Box 58.1

Common causes of hyponatraemia

1 Spurious result

- Isotonic
  - Hyperlipidaemia
  - Hyperproteinaemia
- Hypertonic
  - Hyperglycaemia
  - Mannitol, glycerol, glycine or sorbitol excess

2 Water retention

- Renal failure
- Hepatic failure
- Cardiac failure
- Syndrome of inappropriate ADH secretion
- Drugs
- Psychogenic polydipsia

3 Water retention and salt depletion

- Post-operative, post trauma or patients with excess fluid losses given inappropriate fluid replacement
- Adrenocortical failure
- Diuretic excess

ADH , Antidiuretic hormone.

Isotonic hyponatraemia

Plasma normally contains 94% water and 7% solids (5.5% proteins, 1% salts and 0.5% lipids). If the solid phase is elevated significantly (e.g. in hyperlipidaemia or hyperproteinaemia), any device that dilutes a specific amount of plasma for analysis will give falsely lower values for all measured compounds. This effect produces ‘factitious or pseudohyponatraemia' and is associated with a normal measured serum osmolality.[8] The measurement of plasma sodium by an ion-selective electrode is not affected by the volume of plasma 'solids' and therefore 'pseudohyponatraemia' will not occur with this method.[8]

Hypertonic hyponatraemia

In patients who have hypertonicity due to increased amounts of impermeant solutes (e.g. glucose, mannitol, glycerol or sorbitol), a shift of water from the ICF to the ECF occurs to provide osmotic equilibration, thus diluting the ECF sodium. Such resultant hyponatraemia is often associated with an increased measured osmolality. For example in the presence of hyperglycaemia, for every 3 mmol/L rise in glucose, the serum sodium decreases by 1 mmol/L.[9]

Hypotonic hyponatraemia

Hyponatraemia is almost always caused by an excess of total body water, due to excessive hypotonic or water-generating intravenous (IV) fluids (e.g. 1.5% glycine, 0.45% saline or 5% glucose) or to excessive ingestion of water, particularly in the presence of high circulating ADH concentrations. It may rarely be caused by loss of exchangeable sodium or potassium. In the latter circumstances, a loss of approximately 40 mmol of sodium or potassium, without a change in total body water content, is required to lower the serum sodium by 1 mmol/L. As hyponatraemia may be associated with an alteration in both total body water and total body sodium, the ECF may be increased (hypervolaemia), decreased (hypovolaemia) or exhibit no change (isovolaemia).[5]

In health, a fluid intake of up to 15–20 L may be tolerated before water is retained and hyponatraemia occurs. In psychogenic polydipsia, if the water intake exceeds the renal capacity to form dilute urine, water retention and hyponatraemia will occur. With this disorder, the plasma osmolality exceeds urine osmolality. In circumstances where ADH is increased (e.g. hypovolaemia, hypotension, pain or nausea), or where the renal response to ADH is altered (i.e. in renal, hepatic, pituitary, adrenal or thyroid failure), water retention occurs with lower intakes of fluid.

Specific Causes of Hyponatraemia

Transurethral resection of prostate syndrome

Clinical features

The transurethral resection of prostate (TURP) syndrome consists of hyponatraemia, cardiovascular disturbances (hypertension, hypotension, bradycardia), an altered state of consciousness (agitation, confusion, nausea, vomiting, myoclonic and generalised seizures) and, when using glycine solutions, transient visual disturbances of blurred vision, blindness and fixed dilated pupils, following TURP. It has also been described following endometrial ablation. [10] It may occur within 15 minutes or be delayed for up to 24 hours after surgery, [11] and is usually caused by excess absorption of the irrigating fluid, which contains 1.5% glycine with an osmolality of 200 mOsm/kg. Hyponatraemic syndromes have also been described when surgical irrigating solutions containing 3% mannitol or 3% sorbitol have been used. Symptoms usually occur when greater than 1 L of 1.5% glycine or greater than 2–3 L of 3% mannitol or sorbitol have been absorbed. [12]

The excess absorption of irrigating fluid causes an increase in total body water (which is often associated with only a small decrease in plasma osmolality), hyponatraemia, as glycine, sorbitol or mannitol reduce the sodium component of ECF osmolality. There is also an increase in the osmolar gap, [12] the difference between the measured osmolality and the calculated osmolality. When glycine is used, other features include hyperglycinaemia (up to 20 mmol/L; normal plasma glycine concentrations range from 0.15 to 0.3 mmol/L), hyperserinaemia (as serine is a major metabolite of glycine), hyperammonaemia (following deamination of glycine and serine) and metabolic acidosis and hypocalcaemia (due to the glycine metabolites glyoxylic acid and oxalate). Because glycine is an inhibitory neurotransmitter, and as it passes freely into the intracellular compartment when glycine solutions are used, hyperglycinaemia may be more important in the pathophysiology of this disorder than a reduction in body fluid osmolality and cerebral oedema. [13]

Treatment

Treatment is largely supportive with the management of any reduction in plasma osmolality being based on the measured plasma osmolality and not the plasma sodium. If the measured osmolality is greater than 260 mOsm/kg and mild neurological abnormalities exist, and if the patient is haemodynamically stable with normal renal function, close observation and reassurance (e.g. the visual disturbances are reversible and will last for less than 24 hours) are usually all that is needed. If the patient exhibits haemodynamic instability or severe and unresolving neurological abnormalities, haemodialysis may be warranted. Hypertonic saline is indicated only if the measured osmolality is less than 260 mOsm/kg and severe non-visual neurological abnormalities exist.[14]

Syndrome of inappropriate antidiuretic hormone secretion

This syndrome is a form of hyponatraemia in which there is an increased concentration of ADH inappropriate to any osmotic or volume stimulus that normally affects ADH secretion.[15] Diagnostic criteria and common causes are listed in Boxes 58.2 and 58.3, respectively.

Box 58.2

Criteria for the diagnosis of syndrome of inappropriate antidiuretic hormone

Hypotonic hyponatraemia
Urine osmolality is greater than plasma osmolality
Urine sodium excretion greater than 20 mmol/L
Normal renal, hepatic, cardiac, pituitary, adrenal and thyroid function
Absence of hypotension, hypovolaemia, oedema and drugs affecting ADH secretion
Correction by water restriction

ADH , Antidiuretic hormone.

Box 58.3

Aetiology of syndrome of inappropriate antidiuretic hormone

Ectopic antidiuretic hormone production by tumours

- Small-cell bronchogenic carcinoma
- Adenocarcinoma of the pancreas or duodenum
- Leukaemia
- Lymphoma
- Thymoma

Central nervous system disorders

- Cerebral trauma
- Brain tumour (primary or secondary)
- Meningitis or encephalitis
- Brain abscess
- Subarachnoid haemorrhage
- Acute intermittent porphyria
- Guillain–Barré syndrome
- Systemic lupus erythematosus

Pulmonary diseases

- Viral, fungal and bacterial pneumonias
- Tuberculosis
- Lung abscess

Clinical features

Whereas cerebral manifestations are usually absent when the sodium concentration exceeds 125 mmol/L, progressive symptoms of headache, nausea, confusion, disorientation, coma and seizures may be observed when plasma sodium is below 120 mmol/L, particularly if the decrease in serum sodium concentration occurs rapidly. [16]

Treatment

Initial treatment should be fluid restriction with close monitoring of serum sodium. If serum sodium concentration is not increasing with fluid restriction, judicious administration of sodium as IV normal or hypertonic saline may be required. As the true duration and rapidity of onset of hyponatraemia are often unclear, the presence and severity of symptoms may be used as the trigger for active correction of hyponatraemia. [16] The evidence base available to guide therapy is limited and there is consequently no consensus on the optimum rate at which to correct the serum sodium concentration. The major concern is to avoid neurological damage from untreated seizures, cerebral oedema or myelinolysis. [16] In the absence of good evidence, recommended rates at which to increase the sodium concentration vary from 0.5 to 2 mmol/L/h. Unless the treating clinician feels that more rapid correction is indicated, it seems prudent to correct the serum sodium concentration at a slower rather than a faster rate.

Cerebral salt wasting syndrome

Cerebral salt wasting (CSW) is a syndrome occurring in patients with a cerebral lesion and excess renal loss of sodium and chloride. [17] The exact aetiology of the syndrome remains unclear. Although hyponatraemia is not necessary for the diagnosis, the syndrome is commonly associated with hyponatraemia. [16] The diagnosis of CSW is suspected in patients with a cerebral lesion, such as subarachnoid haemorrhage, traumatic brain injury or a cerebral tumour, when there is an elevated urine output, with elevated urinary sodium in the absence of a physiological cause for increased sodium excretion. [16] The syndrome can be differentiated from the syndrome of inappropriate antidiuretic hormone (SIADH), as patients with CSW and SIADH will have low serum sodium and elevated urinary sodium concentrations, those with CSW will have evidence of ECF depletion (e.g.

negative fluid balance, tachycardia, increased haematocrit, increased urea) as opposed to the SIADH where ECF volume will be normal or slightly expanded.[18] The treatment of patients involves exclusion of other causes of hyponatraemia and increased urine output, replacement of sodium and fluid losses, and possibly fludrocortisone.[19]

Specific Treatments Used for Hyponatraemia

Hypertonic saline

Hypertonic saline, most commonly as 3% saline, is used as a therapy for patients with symptomatic hyponatraemia. Due to the osmolarity (1000 mOsm/L) of 3% saline, it should be given through a central line, and care must be taken to avoid the known complications of its use, including chronic heart failure and central pontine and extrapontine myelinolysis (osmotic demyelination syndrome).[20] Careful haemodynamic and electrolyte monitoring throughout saline administration is required.

Although hypertonic saline has been proposed as a therapy for raised intracranial pressure in a number of clinical settings,[21] its use remains controversial. In a methodologically sound, randomised, clinical trial, which included 229 patients with severe traumatic brain injury, resuscitation with 250 mL of 7.5% saline was not associated with improved mortality or functional outcomes compared with Hartmann's solution.[22]

Vasopressin receptor antagonists

V_2 receptor antagonists, such as lixivaptan and tolvaptan, have recently been developed. These agents come from a novel class of non-peptide agents that bind to V_2 receptors in the distal tubule of the kidney and prevent vasopressin-mediated aquaporin mobilisation, and thus promote aquaresis.[23] These agents have been trialled as therapeutic options for the treatment of hyponatraemia in a number of clinical settings, including hyponatraemia associated with heart failure, cirrhosis and SIADH.[24] The role of V_2 receptor antagonists in the management of hyponatraemia in critically ill patients remains uncertain.

Hypernatraemia

Hypernatraemia, defined as serum sodium greater than 145 mmol/L, is always associated with hyperosmolality and may be caused by excessive administration of sodium salts (bicarbonate or chloride), water depletion or excess sodium with loss of water (Box 58.4).

Box 58.4

Causes of hypernatraemia

Water depletion

- Extrarenal loss
  - Exposure
  - GIT losses (often with excess saline replacement)
- Renal loss
  - Osmotic diuresis – urea, mannitol, glycosuria
  - Diabetes insipidus
    - Neurogenic
      - Post-traumatic, fat embolism
      - Metastatic tumours, craniopharyngioma, pinealoma, cysts
      - Meningitis, encephalitis
      - Granulomas (tuberculosis, sarcoid)
      - Guillain–Barré syndrome
      - Idiopathic
    - Nephrogenic
      - Congenital
      - Hypercalcaemia, hypokalaemia
      - Lithium
      - Pyelonephritis
      - Medullary sponge kidney
      - Polycystic kidney
      - Post-obstructive uropathy
      - Multiple myeloma, amyloid, sarcoid

Salt gain

Administration of hypertonic saline, 0.9% saline or sodium bicarbonate

GIT, Gastrointestinal tract.

Excessive ingestion of sodium salts is rare, but intravenous infusion of large volumes of sodium-containing fluids is common in the management of hospitalised patients. Hypernatraemia often occurs in the recovery phase of acute illness when spontaneous diuresis or diuretic therapy results in more rapid clearance of free water than sodium. Pure water depletion is uncommon unless water restriction is applied to a patient who is unconscious or unable to obtain or ingest water, as the thirst response normally corrects water depletion. If it occurs, the serum sodium concentration increases, in association with the loss of both ECF and ICF.

Clinical features

Hypernatraemia usually produces symptoms if the serum sodium exceeds 155–160 mmol/L (i.e. osmolality >330 mOsm/kg). The clinical features include increased temperature, restlessness, irritability, drowsiness, lethargy, confusion and coma. [25] Convulsions are uncommon. The diminished ECF volume may reduce cardiac output, thereby reducing renal perfusion, and leading to pre-renal renal failure.

Treatment

For pure water depletion, this consists of water administration. If IV fluid is required, 5% glucose or hypotonic saline solution (0.45% saline) can be used, as sterile water infusion causes haemolysis. Since rapid rehydration may give rise to cerebral oedema, the change in serum sodium should be no greater than 0.5 mmol/L/h. [25]

Potassium

Potassium is the principal intracellular cation and accordingly (along with its anion) fulfils the role of the ICF osmotic provider. It also plays a major role in the functioning of excitable tissues (e.g. muscle and nerve). As the cell membrane is 20-fold more permeable to potassium than to sodium ions, potassium is largely responsible for the resting membrane potential. Potassium also influences carbohydrate metabolism and glycogen and protein synthesis.

Total body potassium is 45–50 mmol/kg in the male (3500 mmol/70 kg) and 35–40 mmol/kg (2500 mmol/65 kg) in the female; 95% of the total body potassium is exchangeable. As ECF potassium ranges from 3.1 to 4.2 mmol/L, the total ECF potassium ranges from 55 to 70 mmol. About 90% of the total body potassium is intracellular: 8% resides in bone, 2% in ECF water and 70% in skeletal muscle. With increasing age (and decreasing muscle mass), total body potassium decreases.

Factors Affecting Potassium Metabolism

The potassium content of cells is regulated by a cell wall pump-leak mechanism. Cellular uptake is by the Na^+/K^+ pump, which is driven by Na^+/K^+ ATPase. Movement of potassium out of the cell is governed by passive forces (i.e. cell membrane permeability and chemical and electrical gradients to the potassium ion).

Acidosis promotes a shift of potassium from the ICF to the ECF, whereas alkalosis promotes the reverse shift. Hyperkalaemia stimulates insulin release, which promotes a shift of potassium from the ECF to the ICF, an effect independent of the movement of glucose. β_2-adrenergic agonists promote cellular uptake of potassium by a cyclic adenine monophosphate (AMP)-dependent activation of the Na^+/K^+ pump, whereas α-adrenergic agonists cause a shift of potassium from the ICF to the ECF.[26] Aldosterone increases the renal excretion of potassium; glucocorticoids are also kaliuretic, an effect that may be independent of the mineralocorticoid receptor.

Normally, mechanisms to reduce the ECF potassium concentration (by increasing renal excretion and shifting potassium from the ECF to the ICF) are very effective. However, mechanisms to retain potassium in the presence of potassium depletion are less efficient, particularly when compared with those of sodium conservation. Even with severe potassium depletion, urinary loss of potassium continues at a rate of 10–20 mmol/day. Metabolic alkalosis also enhances renal potassium loss, by encouraging distal nephron Na$^+$/K$^+$, rather than Na$^+$/K$^+$ exchange.

Hypokalaemia

Hypokalaemia is defined as a serum potassium of less than 3.5 mmol/L (or plasma potassium of less than 3.0 mmol/L). It may be due to decreased oral intake, increased renal or gastrointestinal loss, or movement of potassium from the ECF to the ICF (Box 58.5).

Box 58.5

Causes of hypokalaemia

- **Inadequate dietary intake (urine K$^+$ <20 mmol/L)**
- **Abnormal body losses**
  - Gastrointestinal (urine K$^+$ <20 mmol/L)
    - Vomiting, nasogastric aspiration
    - Diarrhoea, fistula loss
    - Villous adenoma of the colon
    - Laxative abuse
  - Renal (urine K$^+$ >20 mmol/L)
    - Conn syndrome
    - Cushing syndrome
    - Bartter syndrome
    - Ectopic ACTH syndrome
      - Small-cell carcinoma of the lung
      - Pancreatic carcinoma
      - Carcinoma of the thymus
  - Drugs
    - Diuretics, particularly, acetazolamide
    - Corticosteroids
    - Carbapenems, amphotericin B, gentamicin
    - Cisplatin

  - Renal tubular acidosis (Type 1 and 2, Type 4 associated with hyperkalaemia)
  - Magnesium deficiency
- **Compartmental shift**
  - Alkalosis
  - Insulin
  - Na^+/K^+ ATPase stimulation
    - Sympathomimetic agents with β2 effect
    - Methylxanthines
  - Barium poisoning
  - Hypothermia
  - Toluene intoxication
  - Hypokalaemic periodic paralysis
  - Delayed following blood transfusion (see Chapter 112)

ACTH , Adrenocorticotropic hormone.

Clinical features

These include weakness, hypotonicity, depression, constipation, paralytic ileus, ventilatory failure, ventricular tachycardias (characteristically Torsades de pointes), atrial tachycardias and even coma. [26] With prolonged and severe potassium deficiency, rhabdomyolysis, thirst and polyuria, due to the development of renal diabetes insipidus, may occur. The electrocardiograph (ECG) changes are relatively non-specific and include prolongation of the PR interval, T-wave inversion and prominent U-waves.

Treatment

IV or oral potassium chloride will correct hypokalaemia, particularly if it is associated with metabolic alkalosis. If the patient has renal tubular acidosis and hypokalaemia, potassium acetate or citrate may be preferred to potassium chloride. IV administration of potassium should normally not exceed 40 mmol/h, and plasma potassium should be monitored at 1 to 4 hourly intervals. [27] In patients with acute myocardial infarction and hypokalaemia, traditional recommendations were to maintain the serum potassium at ≥4.0 mmol/L, but more recently the need to administer supplemental potassium when the serum potassium is greater than 3.5 mmol/L has been questioned. [28]

Hyperkalaemia

Hyperkalaemia is defined as serum potassium greater than 5.0 mmol/L or plasma potassium greater than 4.5 mmol/L. It may be artefactual (from sampling errors such as in vitro haemolysis); true hyperkalaemia may be due to excessive intake, severe tissue damage, decreased excretion or body fluid compartment shift (Box 58.6).

Box 58.6

Causes of hyperkalaemia

Collection abnormalities

- **Delay in separating RBC**
- **Specimen haemolysis**
- **Thrombocythaemia**

Excessive intake

- Transiently following blood transfusion (see Chapter 112)
- Exogenous (i.e. IV or oral KCl, massive blood transfusion)
- Endogenous (i.e. tissue damage)
  - Burns, trauma
  - Rhabdomyolysis
  - Tumour lysis

Decrease in renal excretion

- Drugs
  - Spironolactone, triamterene, amiloride
  - Indomethacin
  - Captopril, enalapril

Renal failure
Addison disease
Hyporeninaemic hypoaldosteronism

Compartmental shift

Acidosis
Insulin deficiency
Digoxin overdosage
Succinylcholine
Arginine hydrochloride
Hyperkalaemic periodic paralysis
Fluoride poisoning

IV , Intravenous; *RBC* , red blood cells.

Clinical features

These include tingling, paraesthesia, weakness, flaccid paralysis, hypotension and bradycardia. The characteristic ECG effects include peaking of the T-waves, flattening of the P-wave, prolongation of the PR interval (until sinus arrest with nodal rhythm occurs), widening of the QRS complex, and the development of a deep S-wave. Finally, a sine wave ECG pattern that deteriorates to asystole may occur at serum potassium levels of 7 mmol/L or greater.

Treatment

This is directed at the underlying cause and may include dialysis. Rapid management of life-threatening hyperkalaemia may be achieved by [29] :

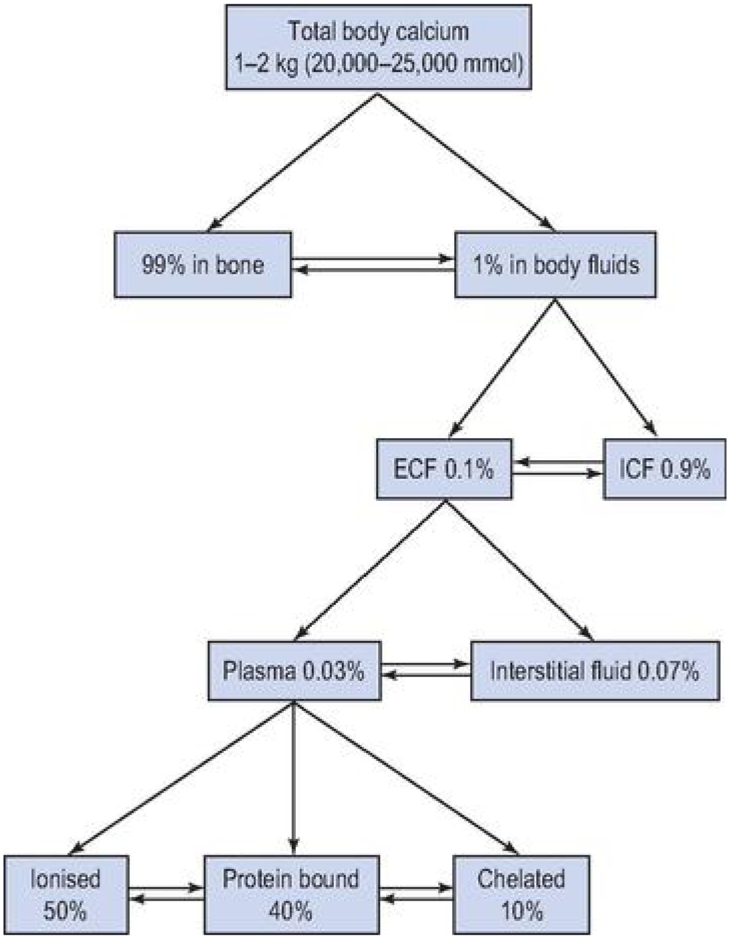
- Calcium chloride or calcium gluconate 10 mL IV of 10% (which is used to reduce the cardiac effects of hyperkalaemia)
- Sodium bicarbonate, 50–100 mmol IV
- Glucose, 50 g IV with 10–15 units of soluble insulin
- Oral and rectal resonium A, 50 g

- Diuresis with frusemide, 40–80 mg IV
- β-agonists; for example salbutamol 5–10 mg nebulised.

Calcium

Calcium is the most abundant extracellular cation which has numerous vital physiological roles, including cell-to-cell signalling, membrane potential, neuro-transmission and blood coagulation.[30, 31] A total of 1–2 kg is present in the average adult, of which 99% is found in the bones and teeth, and only a tenth in the extracellular fluid (ECF). Of the 1% of total calcium present in the circulation, 40% is bound to proteins, 10% is bound to organic anions, and 50% is ionised. Intracellular calcium gradient is maintained by Ca^{2+}/H^{+} ATPases and Na^{+}/Ca^{2+} exchangers.[32]

A schematic illustration of calcium distribution within the various body compartments is shown in Fig. 58.2 .



Total body calcium
1–2 kg (20,000–25,000 mmol)
99% in bone
1% in body fluids
ECF 0.1%
ICF 0.9%
Plasma 0.03%
Interstitial fluid 0.07%
Ionised 50%
Protein bound 40%
Chelated 10%

The hierarchical flowchart depicts total body calcium distribution, which ranges from 1 to 2 kilograms. At the top, 99 percent is stored in bone and 1 percent in body fluids. Of the 1 percent in fluids, 0.1 percent is extracellular fluid and 0.9 per cent is intracellular fluid. The E C F portion further divides into 0.03 percent plasma and 0.07 percent interstitial fluid. Plasma is subdivided into 50 percent ionised, 40 percent protein-bound, and 10 percent chelated. Arrows indicate bidirectional exchanges between subdivisions.

FIG. 58.2 Distribution of body calcium. *ECF* , Extracellular fluid; *ICF* , intracellular fluid.

Ionised calcium is the biologically active component of ECF calcium with respect to physiological functions (Box 58.7) and is the driver for the regulation of calcium homeostasis, and therefore its measurement is key to the management of calcium perturbations, particularly in critical illness.

Box 58.7

Functions of calcium

Excitation – contraction coupling in cardiac, skeletal and smooth muscle
Cardiac action potentials and pacemaker activity
Release of neurotransmitters
Coagulation of blood
Bone formation and metabolism
Hormone release
Ciliary motility
Catecholamine responsiveness at the receptor site
Role as a strong cation
Regulation of cell growth and apoptosis

Regulation of Calcium Homeostasis

Calcium homeostasis is regulated by three factors: parathyroid hormone (PTH), vitamin D and calcitonin. Calcium level is the main determinant for PTH production and release, which exerts negative feedback on the parathyroid glands. In the bones, PTH increases the activity and number of osteoclasts, thus increasing bone resorption of calcium and phosphorus. In the kidneys, it stimulates tubular calcium reabsorption and phosphorus excretion and increases renal hydroxylation of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D. [32]

Alterations in serum protein, pH, serum phosphate and magnesium closely impact on serum calcium concentrations. Plasma calcium levels vary with alterations in plasma protein concentration. A simplified correction is made for hypoalbuminaemia by adding 0.2 mmol/L to the measured serum calcium concentration for every 10 g/L decrease in serum albumin concentration below normal (40 g/L). The corresponding correction factor for globulins is 0.04 mmol/L of serum calcium for every 10 g/L rise in serum globulin. [33]

Changes in pH alter the protein binding of calcium. iCa concentrations can be predicted for a given pH using the following formula:

$$\text{corrected iCa at pH } 7.4 = \text{measured iCa} \times [1 - (0.53)] \times (7.40 - \text{measured pH})$$

Another rule of thumb is that an increase in pH by 0.1 pH units results in a decrease in ionised calcium by approximately 0.1 mmol/L. [34]

Calcium and phosphate are closely linked by the following reaction in the ECF:

$$HPO_4^{2-} + Ca^{2+} = CaHPO_4$$

.

Increases in serum phosphate shift the reaction to the right. When the calcium phosphate solubility product exceeds the critical value of 5 mmol/L, calcium deposition occurs in the tissues, resulting in a fall in serum calcium concentration and a secondary increase in PTH secretion. Reductions in phosphate concentration lead to corresponding changes in the opposite direction.

As magnesium is required for PTH secretion and end-organ responsiveness, alterations in serum magnesium have an impact on serum calcium concentration.

Although the turnover of calcium in the bone is predominantly under the control of PTH and calcitriol, prostaglandins and some of the cytokines also play a role. Bone resorption is mediated by osteoclasts, while osteoblasts are involved in bone formation. The daily calcium balance is summarised in Table 58.8 .

Table 58.8

Measurement of Serum Calcium

The normal total plasma concentration is 2.2–2.6 mmol/L. However, the ionised form (1.1–1.3 mmol/L) is the active fraction and can be measured by most contemporary blood gas analysers. Estimation of ionised calcium from total serum calcium concentration using mathematical algorithms is unreliable in critically ill patients. [35] Calcium levels are reduced by a concomitant lactic acidosis owing to chelation by lactate ion. [36]

Hypocalcaemia

Hypocalcaemia is common in critically ill patients with an estimated incidence of around 70%–90% and is independently associated with a higher mortality when the ionised calcium is less than 0.8 mmol/L. [33], [37]

Spurious hypocalcaemia is seen with poor storage of specimens prior to analysis, resulting in CO_2 loss from the specimen, use of EDTA or large doses of heparin as anticoagulants in the syringe.

Aetiologies

The aetiology of ionised hypocalcaemia based on the predominant pathophysiological mechanism is listed in Box 58.8 . The other contributory mechanisms of hypocalcaemia in each of the conditions are shown in brackets.

Box 58.8

Aetiology of ionised hypocalcaemia

Calcium chelation

Alkalosis (increased binding of calcium by albumin)
Citrate toxicity (calcium chelation)
Massive blood transfusion (citrate leading to calcium chelation)
Hyperphosphataemia (calcium chelation, ectopic calcification, reduced vitamin D3 activity)
Pancreatitis (calcium soap formation, reduced parathyroid secretion)
Tumour lysis syndrome (hyperphosphataemia)
Rhabdomyolysis (hyperphosphataemia and reduced levels of calcitriol)

Hypoparathyroidism

Hypo- and hypermagnesaemia
Sepsis (decreased parathyroid hormone [PTH] secretion, end-organ resistance to PTH, reduced calcitriol production, intracellular shift of calcium, hypomagnesaemia and actions of inflammatory cytokines on the parathyroid glands, kidneys and bone)
Burns (decrease in PTH secretion)
Neck surgery (removal of parathyroid gland, calcitonin release during thyroid surgery and hungry bone syndrome post-parathyroidectomy)

Hypovitaminosis D

Inadequate sun exposure
Inadequate intake
Malabsorption
Liver disease (impaired 25-hydroxylation of cholecalciferol)

Renal failure (impaired 1-hydroxylation of cholecalciferol, hyperphosphataemia)
Medications-phenytoin (inhibition of active calcium transport by intestinal epithelial cells), steroids (increased 24-hydroxylase activity)

Reduced bone turnover

Osteoporosis
Elderly
Cachexia

Drug induced

Bisphosphonates (see under hypercalcaemia)
Propofol
EDTA (calcium chelation)
Ethylene glycol (formation of calcium oxalate crystals in the urine)
Cis-platinum (renal tubular damage leading to hypermagnesuria)
Foscarnet (calcium chelation)
Protamine
Gentamicin (hypermagnesuria leading to hypomagnesaemia and therefore hypocalcaemia)

EDTA , ethylenediaminetetraacetic acid.

Calcium chelation and hypoparathyroidism constitute the common mechanisms of ionised hypocalcaemia in intensive care. Citrate anticoagulation used for renal replacement therapy, if not accompanied by appropriate metabolic monitoring, is another cause of hypocalcaemia in critically ill patients. Frequently, hypocalcaemia is accompanied by a number of other biochemical abnormalities, thus a pattern recognition approach towards the cause of hypocalcaemia will point to its aetiology. Common diagnostic patterns are listed in Table 58.9 .

Table 58.9

Pattern recognition in the diagnosis of common causes of hypocalcaemia

AETIOLOGY OF HYPOCALCAEMIA	CLINICAL/BIOCHEMICAL PATTERNS
Low serum albumin	Reduced total calcium, normal ionised calcium
Alkalosis	Normal total calcium, reduced ionised calcium
Hypomagnesaemia	Reduced ionised calcium and hypokalaemia
Pancreatitis	Hypocalcaemia, elevated serum lipase and glucose
Renal failure	Elevated blood urea nitrogen, elevated phosphate
Rhabdomyolysis	Hypocalcaemia, elevated phosphate, creatine kinase (CK) and urinary myoglobin
Tumour lysis syndrome	Hypocalcaemia, elevated phosphate, potassium and urate
Citrate toxicity	Low-ionised calcium with high total calcium

While alkalosis is frequently associated with ionised hypocalcaemia, the presence of a metabolic acidosis in the face of low serum ionised calcium narrows the differential diagnosis even further (Box 58.9).

Box 58.9

Hypocalcaemia with metabolic acidosis

Acute renal failure
Tumour lysis
Rhabdomyolysis
Pancreatitis
Ethylene glycol poisoning
Hydrofluoric acid intoxication

Clinical Manifestations of Hypocalcaemia

Mild degrees of hypocalcaemia are usually asymptomatic. Ionised calcium levels less than 0.8 mmol/L may cause neuromuscular irritability and result in clinical symptoms. Some of the clinical manifestations of hypocalcaemia seen in the critical care setting are summarised in Box 58.10 .

Box 58.10

Clinical manifestations of hypocalcaemia

Central nervous system

Circumoral and peripheral paraesthesia
Muscle cramps
Tetany
Seizures
Extrapyramidal manifestations: tremor, ataxia, dystonia
Proximal myopathy
Depression, anxiety, psychosis

Cardiovascular

Arrhythmias
Hypotension, inotrope unresponsiveness
Prolonged QT intervals, T-wave inversion
Loss of digitalis effect

Respiratory

- Apnoea
- Laryngospasm
- Bronchospasm

When eliciting tetany, Trousseau's sign (carpopedal spasm) is more specific for hypocalcaemia than Chvostek's sign (facial twitch in response to facial nerve stimulus, present in 10–30% of the normal population). Electrocardiographic changes do not correlate well with the degree of hypocalcaemia. The symptoms of hypocalcaemia are exacerbated by a co-existing hypokalaemia and hypomagnesaemia.

Laboratory workup should include serum calcium, phosphorus, magnesium and alkaline phosphatase, PTH and vitamin D assays and renal function assessment.

Approach to the Treatment of Asymptomatic and Symptomatic Hypocalcaemia

Ionised hypocalcaemia may increase cytosolic calcium and lead to disruption of intracellular processes, activation of proteases and lead to ischaemia-reperfusion injury. Most clinicians agree that an ionised calcium level of less than 0.8 mmol/L needs correction even if asymptomatic.

Management of Acute Symptomatic Hypocalcaemia

Acute symptomatic hypocalcaemia is a medical emergency that requires immediate therapy. In addition to treatment of the underlying cause, the definitive treatment includes the administration of intravenous calcium. Intravenous calcium is available as a calcium salt of chloride or gluconate or acetate. The main difference between these formulations is the amount of elemental calcium available at equivalent volumes of drug (Table 58.10). The dose of calcium required should be based on the elemental calcium. Intravenous calcium can be administered as a bolus or as an infusion. Rapid administration of calcium may cause nausea, flushing, headache and arrhythmias. Digitalis toxicity may be precipitated. Calcium chloride may be better than calcium gluconate for the management of hypocalcaemia, if there is concomitant alkalosis. Following an initial bolus, an infusion may be commenced at a rate of 1–2 mg/kg/h of elemental calcium to maintain target levels of ionised calcium. With correction of the underlying disorder and restoration of calcium to normal levels, the infusion can be tapered and stopped. Adequacy of calcium therapy can be monitored clinically and by performing serial determinations of ionised calcium. Failure of ionised calcium to increase after the commencement of IV calcium may indicate an underlying magnesium deficiency. Administration of calcium in the setting of hyperphosphataemia may result in calcium precipitation in the tissues. In these situations, a phosphate binder may be administered. Calcium salts should not be administered with bicarbonate since the two precipitate. The other indications for calcium administration are listed in Box 58.11 .

Table 58.10

Commonly used intravenous calcium preparations

PREPARATION	DOSAGE	ELEMENTAL CALCIUM/GRAM
Calcium gluconate	10 mL	93 mg (2.3 mmol)
Calcium chloride	10 mL	272 mg (6.8 mmol)
Calcium acetate		253 mg (6.35 mmol)

Box 58.11

Indications for calcium administration

Absolute

Symptomatic hypocalcaemia
Ionised Ca <0.8 mmol/L
Hyperkalaemia
Ca channel blocker overdose

Relative

Beta-blocker overdose
Hypermagnesaemia
Hypocalcaemia in the face of high inotrope requirement
Massive blood transfusion post cardiopulmonary bypass to augment cardiac contractility

In post-operative hypocalcaemia and other cases of hypoparathyroidism, treatment consists of vitamin D therapy. Doses should be approximately 0.25–0.5 micrograms per day of calcitriol.

Hypercalcaemia in Critically Ill Patients

Depending on the patient population, the reported incidence ranges from 3% to 5% to as high as 32% and is significantly less common than hypocalcaemia in critical illness. [37] Although a number of aetiologies have been described (Box 58.12) in the critical care setting, it is usually due to malignancy-related hypercalcaemia, immobilisation, renal failure or post-hypocalcaemic hypercalcaemia. [38] Falsely high measurement of calcium can result from inadvertent haemoconcentration during venipuncture and elevation in serum protein, although ionised calcium levels are not affected. [39] *Pseudohypercalcaemia* has also been described in the setting of essential thrombocythaemia. [40]

Box 58.12

Causes of hypercalcaemia

Common causes of hypercalcaemia in the critically ill patient

Complication of malignancy
- Bony metastases
- Humoral hypercalcaemia of malignancy

Posthypocalcaemic hypercalcaemia
- Recovery from pancreatitis
- Recovery from acute renal failure following rhabdomyolysis

Primary hyperparathyroidism
Adrenal insufficiency
Prolonged immobilisation
Disorders of magnesium metabolism
Use of total parenteral nutrition (TPN)
Hypovolaemia
Iatrogenic calcium administration

Less common causes of hypercalcaemia in the critically ill patient

Granulomatous diseases – sarcoidosis, tuberculosis, berylliosis
Vitamin A & D intoxication
Multiple myeloma
Endocrine:
- Thyrotoxicosis
- Acromegaly
- Phaeochromocytoma

Lithium – chronic therapy
Tamoxifen
Thiazides
Rare association between drugs and hypercalcaemia
Theophylline, omeprazole and growth hormone therapy

Mechanisms of Hypercalcaemia

There are a number of mechanisms that can lead to hypercalcaemia. Malignancy-related hypercalcaemia might arise from bony metastases or humoral hypercalcaemia of malignancy. In the latter (seen with bronchogenic carcinoma and hypernephroma), tumour osteolysis of bone resulting from the release of PTH-like substances, calcitriol, osteoclast activating factor and prostaglandins is thought to be the major underlying mechanism. Aggravating factors include dehydration, immobilisation and renal failure. Immobilisation hypercalcaemia results from an alteration in the balance between bone formation and resorption. This leads to loss of bone minerals, hypercalcaemia, hypercalciuria and increased risk of renal failure. [41] Intravascular volume depletion reduces renal calcium excretion by a combination of reduced glomerular filtration and increased tubular reabsorption of calcium. Hypercalcaemia further compounds this problem by causing a concentrating defect in the renal tubules, thus creating a polyuria and further aggravating the hypovolaemia. Extrarenal production of calcitriol by lymphocytes in granulomata is thought to be the predominant mechanism of hypercalcaemia in granulomatous diseases. Hypercalcaemia can be associated with the use of certain medications – vitamin D toxicity, loop diuretics, thiazide diuretics and lithium.

Manifestations of Hypercalcaemia

The clinical manifestations of hypercalcaemia (commonly encountered when total serum calcium exceeds 3 mmol/L) are outlined in Box 58.13 . *Hypercalcaemic crisis* is defined as severe hypercalcaemia (total serum Ca >3.5 mmol/L) associated with acute symptoms and signs.

Box 58.13

Clinical manifestations of hypercalcaemia

Cardiovascular

- Hypertension
- Arrhythmias
- Digitalis sensitivity
- Catecholamine resistance

Urinary system

- Nephrocalcinosis
- Nephrolithiasis

- Tubular dysfunction
- Renal failure

Gastrointestinal

- Anorexia/nausea/vomiting
- Constipation
- Peptic ulcer
- Pancreatitis

Neuromuscular

- Weakness

Neuropsychiatric

- Depression
- Disorientation
- Psychosis
- Coma
- Seizures

Ectopic calcification is usually seen with chronic hypercalcaemia.

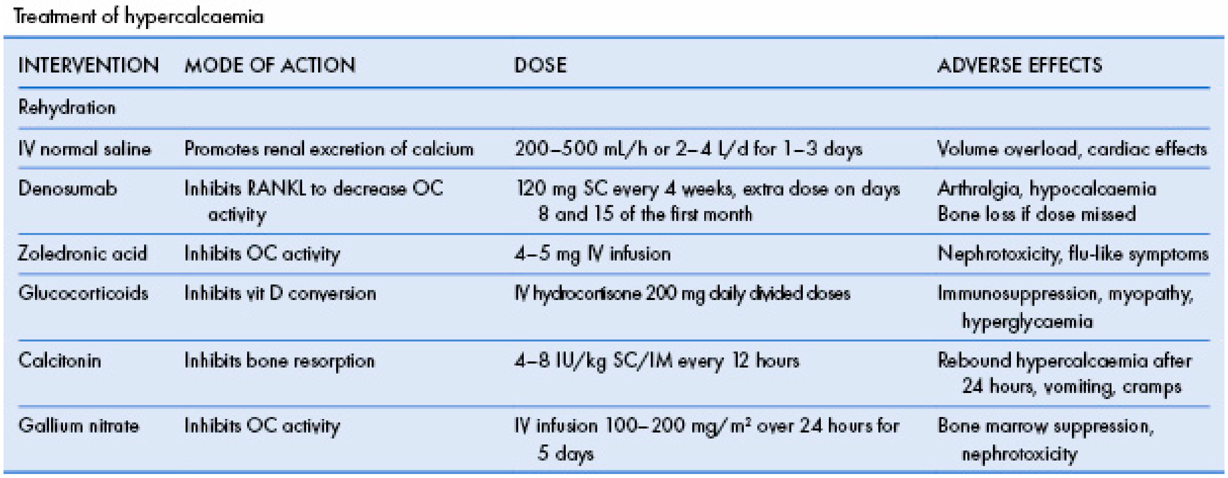
Investigations

The basic workup should include serum calcium, phosphorus and alkaline phosphatase estimation, PTH assay, renal function assessment and a skeletal survey.

Therapy of Hypercalcaemia and Hypercalcaemic Crisis (Table 58.11)

Mild asymptomatic hypercalcaemia does not require emergent treatment. Therapy is usually directed at the underlying cause.

Table 58.11



Treatment of hypercalcaemia

INTERVENTION	MODE OF ACTION	DOSE	ADVERSE EFFECTS
Rehydration			
IV normal saline	Promotes renal excretion of calcium	200–500 mL/h or 2–4 L/d for 1–3 days	Volume overload, cardiac effects
Denosumab	Inhibits RANKL to decrease OC activity	120 mg SC every 4 weeks, extra dose on days 8 and 15 of the first month	Arthralgia, hypocalcaemia Bone loss if dose missed
Zoledronic acid	Inhibits OC activity	4–5 mg IV infusion	Nephrotoxicity, flu-like symptoms
Glucocorticoids	Inhibits vit D conversion	IV hydrocortisone 200 mg daily divided doses	Immunosuppression, myopathy, hyperglycaemia
Calcitonin	Inhibits bone resorption	4–8 IU/kg SC/IM every 12 hours	Rebound hypercalcaemia after 24 hours, vomiting, cramps
Gallium nitrate	Inhibits OC activity	IV infusion 100–200 mg/m² over 24 hours for 5 days	Bone marrow suppression, nephrotoxicity

IM , Intramuscular, *IV* , intravenous, *OC* , osteoclast, *RANKL* , receptor activator of nuclear factor kappa beta (NFkB) ligand, *SC* , subcutaneous.

The management of a hypercalcaemic crisis consists of two principal components:

1. Increasing urinary excretion of calcium.
2. Reducing bone resorption.

Increasing Urinary Excretion of Calcium

As almost all patients with hypercalcaemia are volume depleted, the initial therapy consists of rehydration with normal saline which improves intravascular volume, reduces serum calcium by extracellular dilution and saliuresis promotes calcium loss in the urine. There is very little evidence to support the efficacy and safety of the use of furosemide as an adjunct to promote diuresis. In most patients, these measures would achieve a reduction in serum calcium by about 0.4–0.5 mmol/L. Hypokalaemia, hypomagnesaemia and calcium stone formation in the urine are potential side effects of this mode of treatment. In patients with established renal failure in whom forced diuresis cannot be instituted, dialysis against a dialysate with zero or low calcium concentrations should be the treatment of choice. [42]

Reduction of Bone Resorption

The anti-resorptive drugs, bisphosphonates and denosumab are widely used. Their efficacy, combined with a relative lack of side effects, make them the agents of choice for the treatment of malignancy-related hypercalcaemia, where denosumab is now recommended over bisphosphonates in guidelines. [42]

A combination of calcitonin with one of these anti-resorptives is recommended in the case of severe hypercalcaemia of malignancy. The addition of a calcimimetic drug (cinacalcet) is recommended if effective correction is not achieved.

Other drugs that have been used in the management of hypercalcaemia include prostaglandin inhibitors for cancer-related hypercalcaemia, ketoconazole and chloroquine (for sarcoid-induced hypercalcaemia) and glucocorticoids for granulomatous disease-related hypercalcaemia.

Adjunct Measures in the Management of Hypercalcaemia

Monitoring of cardio-respiratory function and biochemical status is mandatory during therapy of hypercalcaemia. Thiazide diuretics, vitamin D and absorbable antacids should be avoided. Hypercalcaemia potentiates digitalis effect and dosage should be adjusted accordingly. Endocrinologists should be consulted for further management.

Vitamin D Supplementation in Critical Illness

The traditional role of vitamin D has been thought to be the maintenance of adequate serum calcium and phosphate levels, for bone mineralisation and optimal cardiac and skeletal muscle function. More recently, data from biochemical and molecular genetic studies indicate that vitamin D has a much wider range of effects than this traditional role. This is due to the activation of 1,25-dihydroxy-vitamin D in many tissues (in addition to the known activation in the kidneys) by tissue 1-alpha-hydroxylase and the action of this activated form on target tissue mediated by binding to vitamin D binding receptors, which are now known to exist on a myriad of tissues.

These non-skeletal effects, termed pleiotropic, include potentiation of antimicrobial action, modification of inflammation, cardioprotective effects and immunomodulatory effects. [43] Low vitamin D levels (<50 nmol/L) are highly prevalent in critically ill patients (40%–70%) and have been associated with poor outcomes including increased length of stay, longer duration of mechanical ventilation, higher incidence of sepsis and higher mortality rates. While individual randomised controlled trials of supplementation in these patients have not definitively shown benefit, a recent meta-analysis showed that vitamin D administration was associated with lower mortality. [44] However, heterogeneity and certainty assessment of the studies limits overall generalisability. Heterogeneity is contributed to by the varying dosing regimens in these studies.

Magnesium

Magnesium is primarily an intracellular ion that acts as a metallo-coenzyme in numerous phosphate transfer reactions. It has a critical role in the transfer, storage and use of energy.

In humans, the total body magnesium content is 1000 mmol, and plasma concentrations range from 0.70 to 0.95 mmol/L. The daily oral intake is 8–20 mmol (40% of which is absorbed) and the urinary loss, which is the major source of excretion of magnesium, varies from 2.5 to 8 mmol/day. [45]

Hypomagnesaemia

Hypomagnesaemia is caused by decreased intake or increased loss (Box 58.14). Clinical features include neurological signs of confusion, irritability, delirium tremors, convulsions and tachyarrhythmias. Hypomagnesaemia is often associated with resistant hypokalaemia and hypocalcaemia. Treatment consists of IV magnesium sulphate as a bolus of 10 mmol administered over 5 minutes, followed by 20–60 mmol/day.

Box 58.14

Causes of magnesium deficiency

- Gastrointestinal disorders
  - Malabsorption syndromes
  - GIT fistulas
  - Short-bowel syndrome
  - Prolonged nasogastric suction
  - Diarrhoea
  - Pancreatitis
  - Parenteral nutrition
- Alcoholism
- Endocrine disorders
  - Hyperparathyroidism
  - Hyperthyroidism
  - Conn syndrome
  - Diabetes mellitus
  - Hyperaldosteronism
- Renal diseases
  - Renal tubular acidosis
  - Diuretic phase of acute tubular necrosis
- Drugs
  - Aminoglycosides
  - Carbenicillin, ticarcillin
  - Amphotericin B
  - Diuretics
  - Cis-platinum
  - Ciclosporin

GIT, Gastrointestinal tract.

Hypermagnesaemia

Hypermagnesaemia is often caused by excessive administration of magnesium salts or conventional doses of magnesium in the presence of renal failure. Clinical features include drowsiness, hyporeflexia and coma, vasodilatation and hypotension and conduction defects of sinoatrial and atrioventricular nodal block and asystole may occur. Treatment is directed towards increasing the excretion of the ion, which may require dialysis. IV calcium chloride may be used for rapidly treating cardiac conduction defects.[45]

Magnesium Therapy

There are increasing reports of the use of magnesium as a therapy for a variety of conditions. A randomised, controlled trial of over 10,000 women with pre-eclampsia demonstrated the efficacy of magnesium in the prevention of eclampsia[46]; it is also a recommended treatment for established eclampsia. It has been used to treat atrial fibrillation, to achieve both rate control and reversion to sinus rhythm in a number of settings, including post-cardiac surgery, and in the emergency department.[47,48] Magnesium, given either intravenously or nebulised, may be beneficial for patients with acute severe asthma.[49,50] Magnesium has been investigated for preventing delayed cerebral ischaemia and improving functional outcomes in patients with subarachnoid haemorrhage, but current evidence does not support its routine use for this indication.[51]

Phosphate

While most of the body phosphate exists in bone, 15% is found in the soft tissues as ATP, red blood cell 2,3-DPG, and other cellular structural proteins, including phospholipids, nucleic acids and phosphoproteins. Phosphate also acts as a cellular and urinary buffer.[45]

Hypophosphataemia

Hypophosphataemia may be caused by a decreased intake, increased excretion or intracellular redistribution (Box 58.15). Although hypophosphataemia is generally symptom-free, clinical features have been described that include paraesthesia, muscle weakness, seizures, coma, rhabdomyolysis and cardiac failure. Hypophosphataemia may be a prominent feature of the refeeding syndrome when it may be accompanied by other electrolyte disturbances such as hypokalaemia and hypomagnesaemia. Treatment consists of close monitoring and replacement as oral or IV sodium or potassium phosphate, 50–100 mmol/24 h.

Box 58.15

Causes of hypophosphataemia

Hyperparathyroidism
Vitamin D deficiency
Vitamin D-resistant rickets
Renal tubular acidosis
Alkalosis
Parenteral nutrition
Alcoholism
Refeeding syndrome

Hyperphosphataemia

Hyperphosphataemia is usually caused by an increased intake or decreased excretion and is common in both acute and chronic renal failure (Box 58.16). Clinical features include ectopic calcification of nephrocalcinosis, nephrolithiasis and band keratopathy. Treatment may require haemodialysis; otherwise, oral aluminium hydroxide and even hypertonic glucose solutions to shift ECF phosphate into the ICF can be used.

Box 58.16

Causes of hyperphosphataemia

Rhabdomyolysis
Renal failure (acute or chronic)
Vitamin D toxicity
Acidosis
Tumour lysis
Hypoparathyroidism
Pseudohypoparathyroidism
Diphosphonate (bisphosphonate) therapy

Excess intravenous administration

Fluid and Electrolyte Replacement Therapy

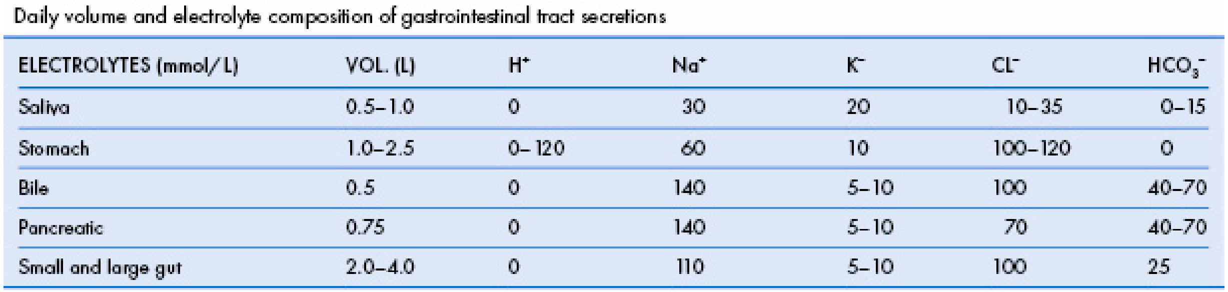
General Principles

In critical illness, many of the body's normal homeostatic mechanisms are deranged and basic life-preserving senses, such as hunger and thirst, may be abolished by disease processes or by treatments such as the use of sedation. As a result, the survival of critically ill patients depends on the administration of appropriate volumes of fluids, and appropriate quantities of electrolytes and nutrition by their medical and nursing attendants. In addition to basal requirements, many critically ill patients have abnormal fluid and electrolyte losses that must be replaced; examples are discussed below.

Gastrointestinal Losses

The daily volumes and composition of gastrointestinal tract (GIT) secretions in mmol/L are shown in Table 58.12 . Clinical effects of fluid loss from the GIT are largely determined by the volume and composition of the fluid, and therapy is usually directed at replacing the losses. Gastric fluid loss (e.g. from vomiting and nasogastric suction) results in water, sodium, hydrogen ion, potassium and chloride depletion. Hence metabolic alkalosis, hypokalaemia, hypotension and dehydration develop if the saline and potassium chloride losses are not correctly replaced.

Table 58.12



Daily volume and electrolyte composition of gastrointestinal tract secretions

ELECTROLYTES (mmol/ L)	VOL. (L)	H^+	Na^+	K^-	CL^-	HCO_3^-
Saliva	0.5–1.0	0	30	20	10–35	0–15
Stomach	1.0–2.5	0–120	60	10	100–120	0
Bile	0.5	0	140	5–10	100	40–70
Pancreatic	0.75	0	140	5–10	70	40–70
Small and large gut	2.0–4.0	0	110	5–10	100	25

Pancreatic and biliary fluid losses (e.g. pancreatic or biliary fistula)

These may result in hyperchloraemic acidosis with hypokalaemia, hypotension and dehydration if the losses of bicarbonate, potassium and saline are not replaced.

Intestinal losses (e.g. fistula or ileostomy losses, diarrhoea and ileus)

These result in hypokalaemia, hypotension and dehydration if the saline and potassium losses are not replaced.

Resuscitation Fluids

Systemic hypotension is a common feature of acute illness and first-line treatment is usually the administration of intravenous resuscitation fluid. The fluids available to clinicians to maintain or expand intravascular volume include crystalloids, colloid solutions and blood products.

Crystalloids are solutions of ions that are capable of passing through semi-permeable membranes; they are inexpensive, have a long shelf life and are usually supplied in plastic containers. Commonly used crystalloids include 0.9% saline and balanced salt solutions such as compound sodium lactate (Hartmann’s), Ringer’s acetate and Ringer’s lactate.

Colloid solutions are suspensions of plasma-derived or semi-synthetic molecules that do not pass through semi-permeable membranes under normal physiological conditions. The theoretical advantage of colloids is that they stay within the intravascular compartment longer due to their increased molecular weight, as a result, less volume is needed for the same effect and there is therefore less potential to produce interstitial oedema. However, the duration of the intravascular effect is variable and dependent on the rate of metabolism and clearance of the different solutions. The most commonly used colloid for resuscitation is human albumin 4%–5%. [52]

Blood products may be used for resuscitation in combination with crystalloids and colloids in patients with major haemorrhage and include fresh frozen plasma and cryoprecipitate.

Whether the choice of resuscitation fluid influences patients' outcomes has been the subject of long-running debate. This debate has been fuelled by the conflicting and inconclusive results of meta-analyses. [53] Data from clinical trials may help guide clinicians with the choice of resuscitation fluids. The Saline versus Albumin Fluid Evaluation (SAFE) Study, found that 0.9% saline and albumin produced comparable outcomes in a heterogeneous population of critically ill adult patients, [54] but in patients with traumatic brain injury resuscitation with albumin was associated with a significant increase in mortality. [55] While hypoalbuminaemia is associated with increased mortality in critically ill patients, there is no convincing evidence that albumin supplementation to correct hypoalbuminaemia reduces mortality or improves other important outcomes. [56] In patients with sepsis, albumin may be beneficial. In a post-hoc analysis of patients with sepsis in the SAFE study, resuscitation with albumin may have reduced mortality. [57] In a post-hoc subgroup analysis in the Albumin Italian Outcomes in Sepsis (ALBIOS) trial, where critically ill adult patients with sepsis and septic shock were assigned to receive 20% albumin and crystalloid versus crystalloid solutions alone, mortality was reduced in the patients with septic shock who were assigned to albumin. [58] The Crystalloid versus Hydroxyethyl Starch Trial study demonstrated no advantage to the use of hydroxyethyl starch (HES) compared to saline in critically ill adult patients, with a greater proportion of those assigned to HES being treated with renal replacement therapy. [59] In a trial led by the Scandinavian Critical Care Trials Group patients with severe sepsis who were resuscitated with HES 130/0.42 in Ringer's acetate had an increased risk of death compared with those resuscitated only with Ringer's acetate. [60] Although rapid fluid resuscitation remains a strongly recommended treatment for adults with severe sepsis in the developed world, a trial in African children with severe infections (primarily malaria) has challenged the assumption that this is the correct strategy in all situations. In the Fluid Expansion as Supportive Therapy study, children with severe infections who received 20–40 mL/kg of either normal saline or 5% albumin as fluid boluses had an increased risk of death compared with those who received only maintenance fluids. [61] The relevance of these findings for adult patients and developed world medicine is unclear.

There have been no large-scale trials comparing the safety and efficacy of gelatins and dextrans with other resuscitation fluids and therefore their role as resuscitation fluids has not been clearly defined and superseded by other fluids with better evidence.

More recently the fluid debate has moved to determining which crystalloids are best for resuscitation and fluid therapy with robust evidence reported in a number of investigator-initiated trials. [62-64] The isotonic Solutions and Major Adverse Renal events Trial (SMART) compared 0.9% saline with balanced crystalloids (lactated Ringer's solution or PlasmaLyte A, chosen at the clinicians' discretion) in a single centre, open-label, multiple crossover, cluster-randomised design. Patients who received balanced crystalloids had lower major adverse kidney events (MAKE) at day 30 compared to those who received saline. [63] In the balanced solution versus Saline in Intensive Care Study (BaSICS) which was conducted in 75 ICUs in Brazil, there was no difference between fluids on 90-day mortality. [64] The Australian and New Zealand Plasma-Lyte 148 versUs Saline (PLUS) study also reported no difference in 90-day mortality between fluids. [62] These data were incorporated into an updated systematic review and meta-analysis, and in the low risk of bias trials, there was a lack of statistically significant results for 90-day mortality for balanced versus saline (risk ratio 0.96, 95% confidence intervals 0.91–1.01, $I^2 = 12.1\%$); however, using Bayesian analysis, there was an 89.5% probability that the use of balanced solutions was associated with lower mortality by some degree, than saline. [65] The current evidence would suggest that crystalloids are generally the first-line fluid of choice for resuscitation and fluid therapy compared with colloids, for critically ill patients.

Disorders of consciousness

Xiuxian Pham, Toby Jeffcote and Andrew Udy

Introduction

Many patients cared for in the intensive care unit (ICU) will have an altered level of consciousness. This is often related to the use of sedative medications, but multiple forms of central nervous system (CNS) disease (e.g. acute brain injuries) and CNS manifestations of systemic disease (e.g. sepsis-induced encephalopathy) can alter neurological function, ranging from mildly disordered cognition to a complete absence of awareness and neurological arousal. The assessment and management of these disorders are typically complicated in the ICU, due to the interaction between iatrogenic and organic causes of disordered consciousness, such as the clinical assessment of the brain-injured patient who has required high-dose sedation for raised intra-cranial pressure.

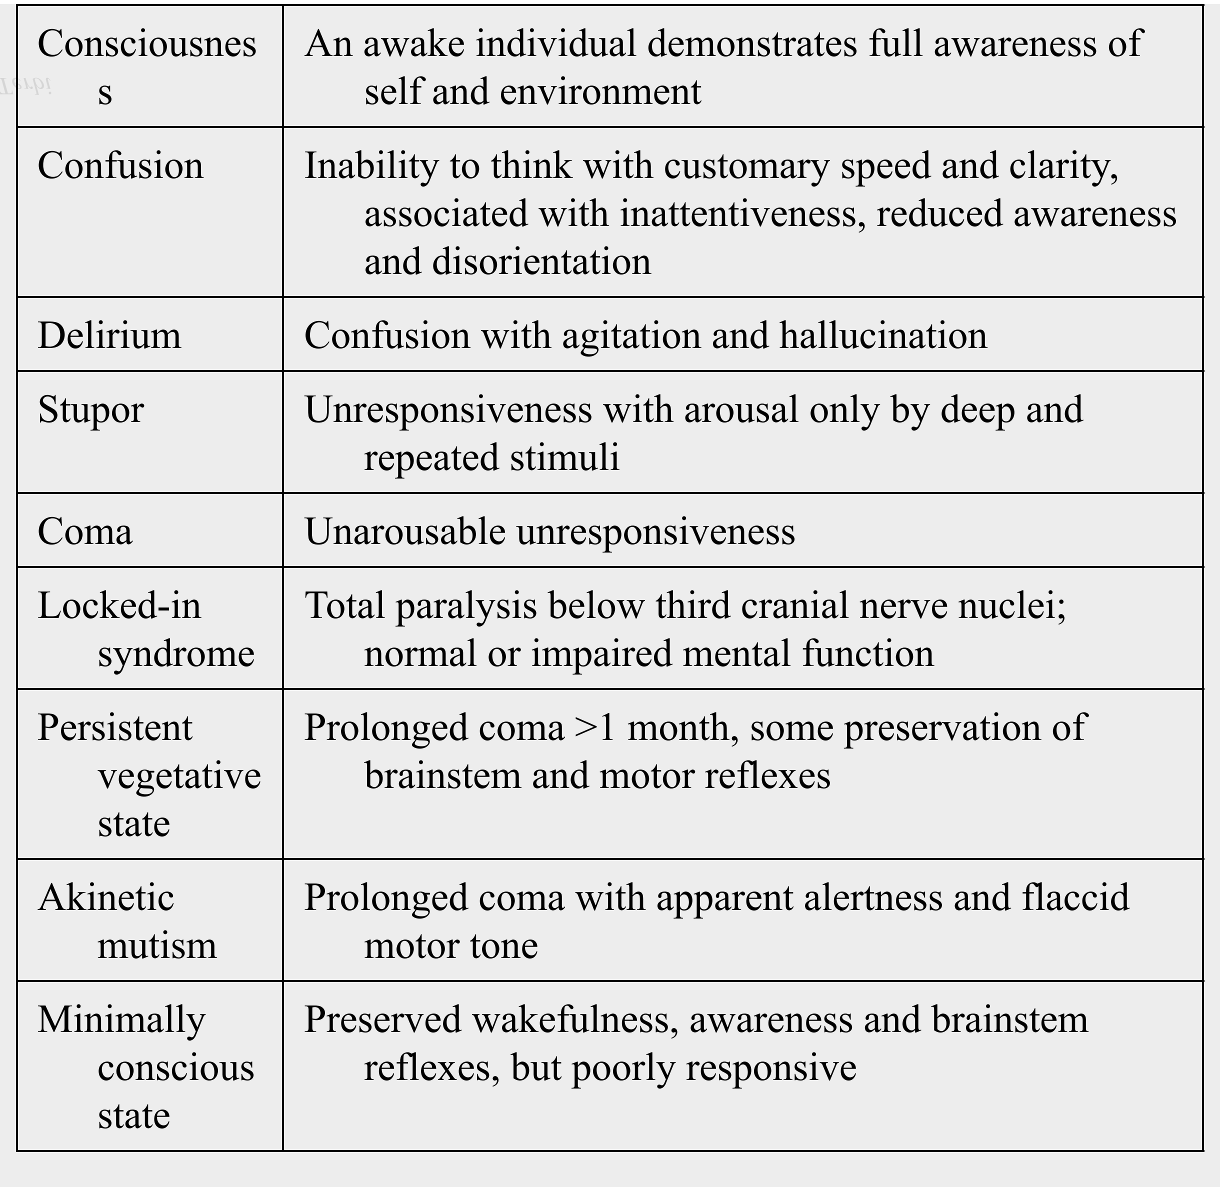
Altered cerebral function has a significant association with poor patient-centred outcomes. This association is evident across the spectrum of acute neurological function and encompasses both the significant impact of severe brain injuries and the profound implications of cognitive dysfunction following episodes of delirium in the ICU. It is important that ICU clinicians are aware of the many causes of altered consciousness and have a structured comprehensive approach to diagnosis and management.

Categorisation of Disorders of Consciousness

Disorders of consciousness can be conceptualised as a range of neurological states differentiated by variation in arousal and awareness. [1] This spectrum of clinical states is illustrated in Box 59.1 and Table 59.1 . Coma is defined by the absence of arousal and awareness not explained by medication or active physiological compromise. Precise diagnosis of coma and coma-like syndromes requires specific knowledge and experience and will often require consultation with other specialty services such as neurology or neurosurgery.

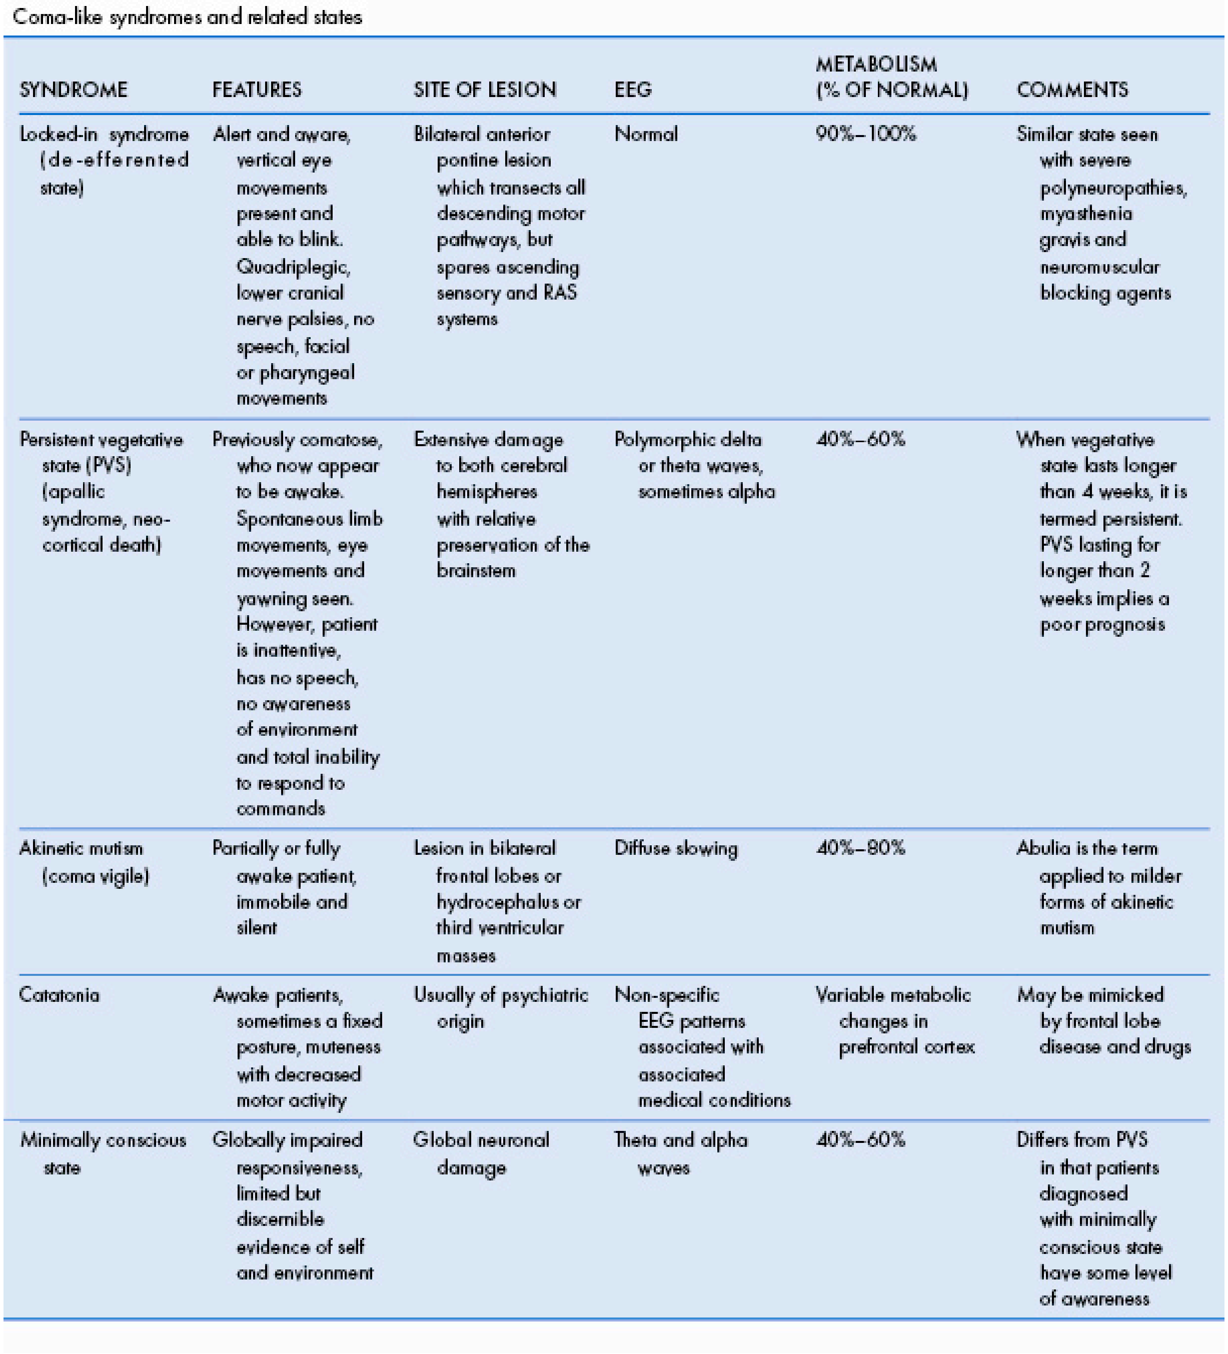
Box 59.1

Disorders of consciousness



Consciousness	An awake individual demonstrates full awareness of self and environment
Confusion	Inability to think with customary speed and clarity, associated with inattentiveness, reduced awareness and disorientation
Delirium	Confusion with agitation and hallucination
Stupor	Unresponsiveness with arousal only by deep and repeated stimuli
Coma	Unarousable unresponsiveness
Locked-in syndrome	Total paralysis below third cranial nerve nuclei; normal or impaired mental function
Persistent vegetative state	Prolonged coma >1 month, some preservation of brainstem and motor reflexes
Akinetic mutism	Prolonged coma with apparent alertness and flaccid motor tone
Minimally conscious state	Preserved wakefulness, awareness and brainstem reflexes, but poorly responsive

Table 59.1



Coma-like syndromes and related states

SYNDROME	FEATURES	SITE OF LESION	EEG	METABOLISM (% OF NORMAL)	COMMENTS
Locked-in syndrome (de-efferented state)	Alert and aware, vertical eye movements present and able to blink. Quadriplegic, lower cranial nerve palsies, no speech, facial or pharyngeal movements	Bilateral anterior pontine lesion which transects all descending motor pathways, but spares ascending sensory and RAS systems	Normal	90%–100%	Similar state seen with severe polyneuropathies, myasthenia gravis and neuromuscular blocking agents
Persistent vegetative state (PVS) (apallic syndrome, neo-cortical death)	Previously comatose, who now appear to be awake. Spontaneous limb movements, eye movements and yawning seen. However, patient is inattentive, has no speech, no awareness of environment and total inability to respond to commands	Extensive damage to both cerebral hemispheres with relative preservation of the brainstem	Polymorphic delta or theta waves, sometimes alpha	40%–60%	When vegetative state lasts longer than 4 weeks, it is termed persistent. PVS lasting for longer than 2 weeks implies a poor prognosis
Akinetic mutism (coma vigile)	Partially or fully awake patient, immobile and silent	Lesion in bilateral frontal lobes or hydrocephalus or third ventricular masses	Diffuse slowing	40%–80%	Abulia is the term applied to milder forms of akinetic mutism
Catatonia	Awake patients, sometimes a fixed posture, muteness with decreased motor activity	Usually of psychiatric origin	Non-specific EEG patterns associated with associated medical conditions	Variable metabolic changes in prefrontal cortex	May be mimicked by frontal lobe disease and drugs
Minimally conscious state	Globally impaired responsiveness, limited but discernible evidence of self and environment	Global neuronal damage	Theta and alpha waves	40%–60%	Differs from PVS in that patients diagnosed with minimally conscious state have some level of awareness

---

EEG , Electroencephalography; *RAS* , reticular-activating system.

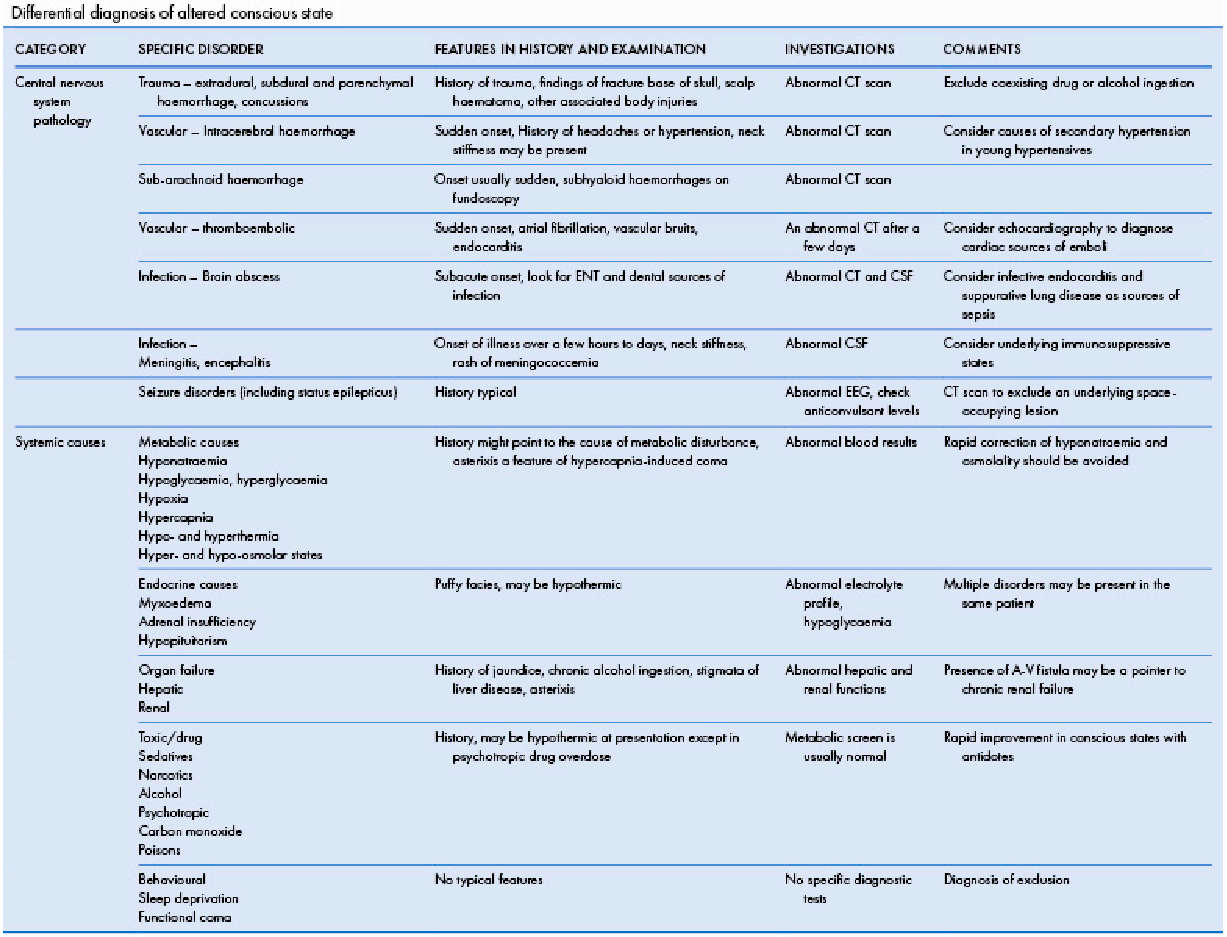
Differential Diagnosis of Disordered Consciousness

Although the aetiology of disordered consciousness is invariably multifactorial in the ICU, the differential diagnosis can be broadly dichotomised into two groups:

1. CNS causes including vascular, traumatic, infective, neoplastic and hypoxic aetiologies.
2. Systemic causes including metabolic, endocrine, toxic and organ failures.

Table 59.2 summarises these sub-divisions

Table 59.2



Differential diagnosis of altered conscious state

CATEGORY	SPECIFIC DISORDER	FEATURES IN HISTORY AND EXAMINATION	INVESTIGATIONS	COMMENTS
Central nervous system pathology	Trauma – extradural, subdural and parenchymal haemorrhage, concussions	History of trauma, findings of fracture base of skull, scalp haematoma, other associated body injuries	Abnormal CT scan	Exclude coexisting drug or alcohol ingestion
	Vascular – Intracerebral haemorrhage	Sudden onset, History of headaches or hypertension, neck stiffness may be present	Abnormal CT scan	Consider causes of secondary hypertension in young hypertensives
	Sub-arachnoid haemorrhage	Onset usually sudden, subhyaloid haemorrhages on fundoscopy	Abnormal CT scan	
	Vascular – thromboembolic	Sudden onset, atrial fibrillation, vascular bruits, endocarditis	An abnormal CT after a few days	Consider echocardiography to diagnose cardiac sources of emboli
	Infection – Brain abscess	Subacute onset, look for ENT and dental sources of infection	Abnormal CT and CSF	Consider infective endocarditis and suppurative lung disease as sources of sepsis
	Infection – Meningitis, encephalitis	Onset of illness over a few hours to days, neck stiffness, rash of meningococcemia	Abnormal CSF	Consider underlying immunosuppressive states
	Seizure disorders (including status epilepticus)	History typical	Abnormal EEG, check anticonvulsant levels	CT scan to exclude an underlying space-occupying lesion
Systemic causes	Metabolic causes Hyponatraemia Hypoglycaemia, hyperglycaemia Hypoxia Hypercapnia Hypo- and hyperthermia Hyper- and hypo-osmolar states	History might point to the cause of metabolic disturbance, asterixis a feature of hypercapnia-induced coma	Abnormal blood results	Rapid correction of hyponatraemia and osmolality should be avoided
	Endocrine causes Myxoedema Adrenal insufficiency Hypopituitarism	Puffy facies, may be hypothermic	Abnormal electrolyte profile, hypoglycaemia	Multiple disorders may be present in the same patient
	Organ failure Hepatic Renal	History of jaundice, chronic alcohol ingestion, stigmata of liver disease, asterixis	Abnormal hepatic and renal functions	Presence of A-V fistula may be a pointer to chronic renal failure
	Toxic/drug Sedatives Narcotics Alcohol Psychotropic Carbon monoxide Poisons	History, may be hypothermic at presentation except in psychotropic drug overdose	Metabolic screen is usually normal	Rapid improvement in conscious states with antidotes
	Behavioural Sleep deprivation Functional coma	No typical features	No specific diagnostic tests	Diagnosis of exclusion

Clinical Assessment of the Unconscious Patient (See also Chapter 9)

A detailed clinical history and examination of the patient presenting with impaired consciousness is crucial in determining aetiology and subsequent management. Obtaining a history directly from the patient is often impossible, but collateral history from bystanders or family members may provide clues as to the cause of the clinical presentation. In addition, although a ‘standard’ neurological examination (such as an assessment of voluntary motor function and/or sensation) may not be possible in a comatose individual, useful information can still be obtained by performing a systematic general examination, and a targeted neurological assessment, with a specific focus on the level of consciousness, brainstem function and motor responses to verbal or noxious stimuli.

History

In emergency cases, the initial focus of clinical assessment should be on the stabilisation of the patient. Once this is achieved the findings from a targeted clinical history and examination can inform the choice and prioritisation of additional diagnostic investigation. Critical details include but are not limited to:

- Location and setting
  - Where did this occur? Were there surrounding environmental clues as to the cause, for example, empty medication packets nearby to suggest risk of overdose, damaged or broken items that may indicate a generalised tonic-clonic seizure?
  - When did this occur? When was the patient last known to be well? Evaluation of ischaemic stroke, for example, requires details of their last known ‘well time’ to determine eligibility for acute reperfusion therapy
- Onset of loss of consciousness or deterioration
  - Was the event sudden, rapidly progressive or gradual?

    - Did the conscious state fluctuate, worsen or remain the same?
- Symptoms or signs preceding loss of consciousness
    - Focal neurological signs such as hemiparesis, dysphasia or ataxia may indicate a structural lesion
    - Abrupt onset of a severe headache may suggest rupture of an intra-cranial aneurysm or arteriovenous malformation, with associated sub-arachnoid haemorrhage
- Past medical history
    - Relevant past medical history increases the pre-test probability of certain conditions, for example, epilepsy, cerebrovascular risk factors (hypertension, hypercholesterolaemia, diabetes, cardiac disease), psychiatric illness, cancer
- Drug and alcohol history
    - Medication lists can provide insight into the patient’s past medical history, including new medications or alteration to dosing regimens. New medications can precipitate a toxidrome, for example, dopaminergic agents and neuroleptic malignant syndrome. Similarly, abrupt cessation of medications may result in rebound symptomatology, for example baclofen cessation and delirium.
    - Quantifying non-prescription medication, recreational drug and alcohol use can provide indications as to the aetiology of the presentation, for example cocaine use and reversible cerebral vasoconstriction syndrome.
- Prior relevant symptoms or presentations
    - Previous transient focal neurological symptoms, for example capsular warning syndrome preceding a stroke or sentinel bleed in sub-arachnoid haemorrhage (SAH)
    - Recent falls, injuries or trauma
    - Recent illnesses, for example diarrhoeal illness and reduced absorption of medications, rash and meningococcal meningitis
    - Systemic symptoms, for example fevers and headaches

Systematic General Examination

Careful systematic examination of the patient may identify the likely aetiology of coma. Generalised skin manifestations may be seen in carbon monoxide poisoning (cherry red discolouration), chronic liver disease (telangiectasia, clubbing, jaundice), hypothyroidism (puffy facies) and hypopituitarism (sallow complexion). The presence of cutaneous petechiae or ecchymoses may indicate meningococcemia, rickettsial infection or endocarditis as possible causes of coma. Needle puncture marks may suggest intravenous drug abuse. Excessively dry skin may indicate diabetic ketoacidosis or anticholinergic overdose.

Periorbital haematomas (raccoon eyes) indicate an anterior basal skull fracture, particularly if there is associated cerebrospinal fluid (CSF) rhinorrhoea. Other signs of basal skull fracture include Battle's sign (bruising confined to the skin over the mastoid from a fracture of the petrous temporal bone) and CSF otorrhoea or bleeding from auditory meatus. Nuchal rigidity may be seen in meningoencephalitis and SAH, although this may not be apparent with deep coma, and is often confounded in the emergency setting. Asterixis can be seen in hepatic or renal failure-associated encephalopathy.

Lacerations to the buccal mucosa or tongue may indicate a recent convulsive seizure resulting in tongue biting. Lateral tongue lacerations are more suggestive of a seizure, whereas lacerations at the tip of the tongue more frequently result from syncope.

The breath may indicate the presence of alcohol or other toxins (garlic-like odour with organophosphates, almond with cyanide). It may also help to identify hepatic failure (fishy odour), uraemia (ammonia or urine-like odour) or ketosis (sweet and fruity odour).

Cardiorespiratory examination is particularly relevant when fever is present. Cardiac murmurs raise the possibility of infective endocarditis, which is associated with both cerebral embolism and intracerebral haemorrhages. Abdominal examination may identify signs of chronic liver failure, such as hepatomegaly and ascites, suggesting hepatic encephalopathy. Palpable kidneys may indicate polycystic kidney disease and should prompt consideration of sub-arachnoid haemorrhage as a possible diagnosis.

Neurologic Examination

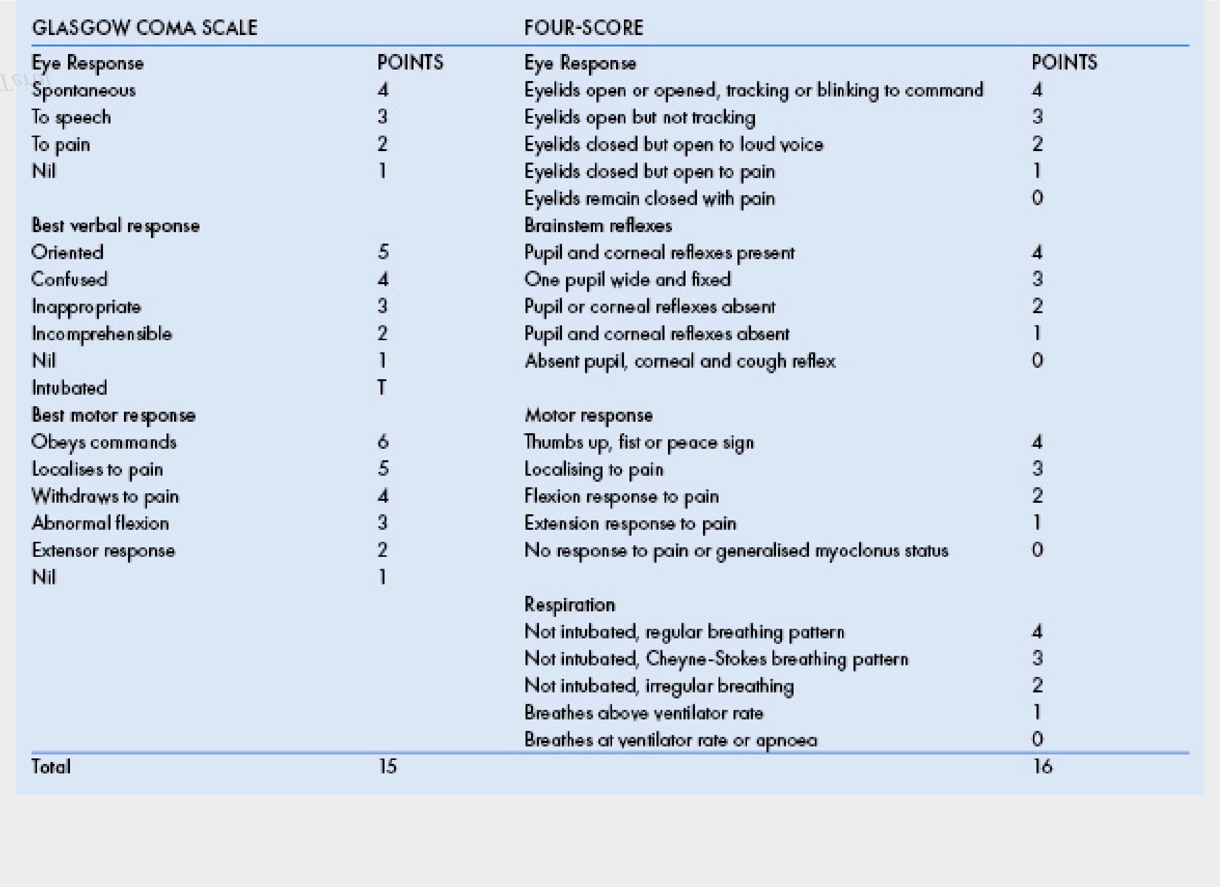
Level of Consciousness

This is assessed by the Glasgow Coma Scale (GCS), which is an assessment of the patient’s response to verbal command and physical stimuli. The GCS (Box 59.2) was originally developed to monitor the level of consciousness post head injury but is now used to describe the depth of coma in almost all cases of impaired consciousness, regardless of aetiology. Whilst the GCS is a simple clinical score easily performed by both medical and nursing staff by the bedside, it has several limitations:

1. To minimise inter-observer variability, the ‘best’ response for each component of the score is used to calculate the overall score. This convention does not identify unilateral or focal neurological changes. Ideally, responses to clinical testing should be recorded in descriptive terms rather than with a simple numerical score and the motor response in all four limbs should be recorded separately.
2. The GCS does not take into account the patient’s physiological state, for example, blood pressure/cerebral perfusion pressure. These factors should be optimised prior to GCS assessment.
3. The GCS does not require specification of confounding factors such as sedative drugs, neuromuscular blocking agents or previous illicit drug or alcohol use. These factors should be recorded alongside any documentation of GCS assessment.
4. Subtle changes in brainstem reflexes are not adequately assessed by the GCS.

Box 59.2

Coma Scales



GLASGOW COMA SCALE		FOUR-SCORE	
Eye Response	POINTS	Eye Response	POINTS
Spontaneous	4	Eyelids open or opened, tracking or blinking to command	4
To speech	3	Eyelids open but not tracking	3
To pain	2	Eyelids closed but open to loud voice	2
Nil	1	Eyelids closed but open to pain	1
		Eyelids remain closed with pain	0
Best verbal response		Brainstem reflexes	
Oriented	5	Pupil and corneal reflexes present	4
Confused	4	One pupil wide and fixed	3
Inappropriate	3	Pupil or corneal reflexes absent	2
Incomprehensible	2	Pupil and corneal reflexes absent	1
Nil	1	Absent pupil, corneal and cough reflex	0
Intubated	T		
Best motor response		Motor response	
Obeys commands	6	Thumbs up, fist or peace sign	4
Localises to pain	5	Localising to pain	3
Withdraws to pain	4	Flexion response to pain	2
Abnormal flexion	3	Extension response to pain	1
Extensor response	2	No response to pain or generalised myoclonus status	0
Nil	1		
		Respiration	
		Not intubated, regular breathing pattern	4
		Not intubated, Cheyne-Stokes breathing pattern	3
		Not intubated, irregular breathing	2
		Breathes above ventilator rate	1
		Breathes at ventilator rate or apnoea	0
Total	15		16

To overcome the limitations of the GCS in assessing brainstem activity, the FOUR (Full Outline of UnResponsiveness) score was proposed by Wijdicks et al. [2] The components of the FOUR score include eye movements, motor score, brainstem reflexes and respiration. Each subcomponent is scored out of a maximum of four and therefore the maximum score is 16. It does not include verbal response and may be more suitable in the intubated patient. The AVPU scale has also been utilised as a rapid way of screening for an altered mental status, particularly in younger children. [3] The scale simplifies the conscious state to: Alert, Verbally Responsive, Painfully Responsive and Unresponsive. Any state below ‘A’ is considered abnormal and warrants prompt evaluation and management.

Cranial Nerves

A limited cranial nerve examination can still be performed in a comatose patient. The presence of normal pupil reactivity to light (2–5 mm and equal in size and demonstrating both direct and consensual light reflexes) confirms the integrity of the pupillary pathway (retina, optic nerve, optic chiasma and tracts, midbrain and third cranial nerve nuclei and nerves). [1] Physiologic anisocoria with unequal pupils by less than 1 mm occurs in 20% of the population, and the difference in pupillary size remains consistent with different degrees of illumination. [4] The size of the pupil is a balance between the opposing influences of both sympathetic (causing dilatation) and parasympathetic (causing constriction) systems. Pupillary abnormalities have localising and diagnostic value in clinical neurology (Table 59.3). [5] When the pupils are small, the light reaction is difficult to appreciate and may require a magnifying glass or the use of automated pupillometry. Pupillary athetosis or hippus (rhythmic, regular contracting and dilating pupillary movements) can be seen physiologically in a drowsy state, or associated with pathological states such as nonconvulsive status epilepticus or diabetic autonomic neuropathy. [6, 7]

Table 59.3

Visualisation of the optic fundi can provide additional diagnostic information. However, the pupils should never be dilated pharmacologically without prior documentation of the pupillary size and the light reflex. The presence of bilateral papilloedema suggests the presence of intra-cranial hypertension although this sign is frequently absent when the lesion is acute. Subhyaloid and vitreous haemorrhages (Terson's syndrome) may be seen in patients with SAH, traumatic brain injury (TBI) and haemorrhagic stroke. [8]

Horizontal eye movements to the contralateral side are initiated in the ipsilateral frontal lobe and are closely coordinated with the corresponding centre in the contralateral pons. To facilitate conjugate eye movements, yoking of the third, fourth and sixth nerve nuclei is achieved by the medial longitudinal fasciculus. To look to the left, the movement originates in the right frontal lobe and is coordinated by the left pontine region and vice versa. In contrast to horizontal gaze, vertical eye movements are under bilateral control of the cortex and upper midbrain.

The position and movements of the eyes are observed at rest. The presence of spontaneous roving eye movements excludes brainstem pathology as a cause of coma. With frontal lobe pathology, the eyes will deviate towards the side of the lesion, whilst in pontine pathologies, the eyes will deviate away from the side of the lesion. Ocular bobbing, an intermittent downward jerking eye movement, is seen in pontine lesions due to loss of horizontal gaze and unopposed midbrain controlled vertical gaze activity. [9] Skew deviation (vertical separation of the ocular axes) occurs with pontine and cerebellar disorders. [10]

The presence of full and conjugate eye movements in response to oculocephalic and oculovestibular stimuli demonstrates the functional integrity of a large segment of the brainstem. The oculocephalic (doll's eyes) manoeuvre is performed by rapidly rotating the head in horizontal and vertical planes, examining the ocular movements. The eyes move in the opposite direction of head rotation if the brainstem pathways are spared. The oculovestibular reflex (caloric testing) is performed when neck manipulation is contraindicated. The head is elevated to 30° from the horizontal (allowing the lateral semicircular canal to be vertical) and the ear canal is irrigated with cold or iced water. In the unconscious patient with intact brainstem pathways, the eyes move towards the irrigated ear. If the patient is conscious, for example in a functional coma, a physiologically normal response is seen with the presence of nystagmus, with the fast phase away from the irrigated ear.

Corneal reflexes are generally preserved in coma. Upward rolling of the eyes after corneal stimulation (Bell's phenomenon) implies intact midbrain and pontine function. The gag reflex assesses the function of the glossopharyngeal (sensory) and vagus nerves (motor). It is tested with stimulation of the posterior pharynx with a tongue depressor but can be absent in normal people and may be difficult to test in the intubated patient. The cough reflex is more commonly employed to assess vagal function as stimulation by tracheal suctioning is more easily achieved at the bedside.

Motor Function

A description of motor function includes any spontaneous activity, and the observed response to stimulation. Restlessness, crossing of legs and spontaneous coughing, yawning and localising movements suggest only a mild depression of the conscious state. Swallowing and hiccups may indicate that the lower brainstem is intact but are among the last motor responses to be abolished. Choreoathetotic or ballistic movements suggest a basal ganglion lesion. Myoclonic movements indicate a metabolic disorder, commonly of post-anoxic origin.

Posturing can be observed spontaneously or in response to a stimulus. The type of motor response is typically elicited using painful stimuli when there is impaired awareness, and the patient may localise to or withdraw from pain. Decorticate posturing usually occurs with lesions above the midbrain, typically in the cerebral white matter. It is characterised by the flexion of the elbows and wrists and extension of the lower limbs. Decerebrate posturing may be seen in a variety of disease states: midbrain lesion, certain metabolic disorders (e.g. hypoglycaemia, anoxia, hepatic coma) and in drug intoxication. This is characterised by stiff extension of the limbs, internal rotation of the arms and plantar flexion of the ankles. With severe rigidity, opisthotonos and jaw clenching may be observed. These movements may be unilateral or bilateral, and spontaneous or in response to a noxious stimulus.

Abnormal movements or posturing may represent motor manifestations of seizure activity and it is therefore important to document the observed movements in descriptive terms, including frequency, rhythmicity and type of movement (unilateral, bilateral, flexion, extension, etc.). Other important details include the presence of any provocative stimulus, stereotypical or repeated motor patterns and the presence of any associated systemic features (e.g. changes to vital signs and diaphoresis).

Motor responses should be assessed in bilateral upper and lower limbs, and centrally. Unilateral weakness or paralysis may raise concern for a cerebral or spinal lesion, for example stroke. Tone, clonus and reflexes including plantar response should be assessed for features indicating an upper or lower motor neuron lesion. Typical upper motor neuron signs include increased tone, clonus and hyperreflexia.

Respiratory System

An abnormal respiratory rate and patterns have been described in coma,[11] but their precise localising value is uncertain. As a general rule, at lighter levels of impaired consciousness tachypnoea predominates, whilst respiratory depression increases with the depth of coma. Some of the commonly observed respiratory abnormalities are summarised in Box 59.3 . Respiratory failure in comatose patients may result from hypoventilation, aspiration pneumonia and neurogenic pulmonary oedema.

Box 59.3

Disorders of respiratory rate and pattern in coma

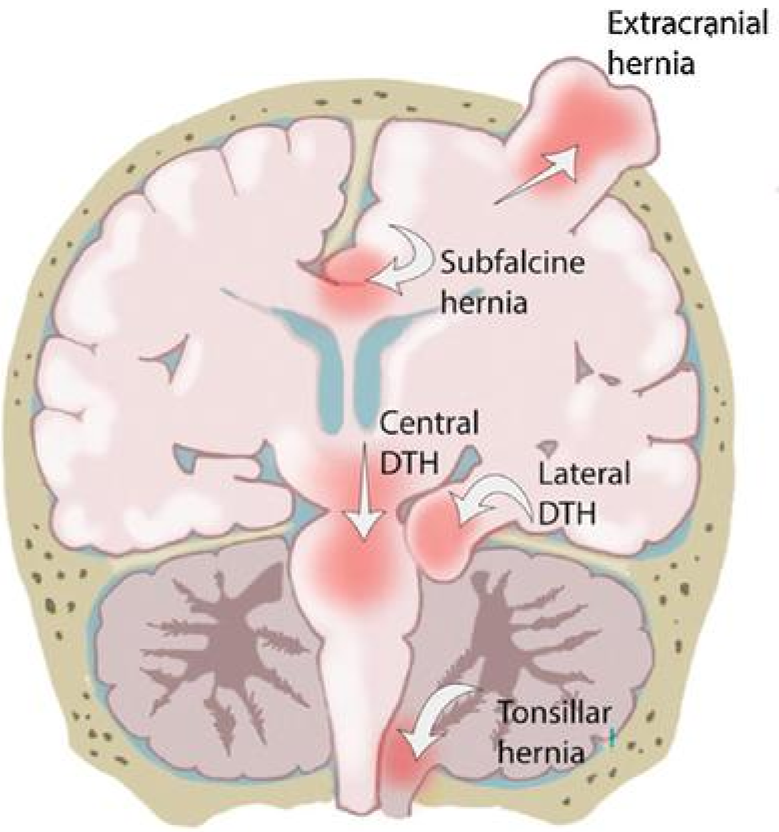
ABNORMALITY	SIGNIFICANCE
Bradypnoea	Drug-induced coma, hypothyroid coma
Tachypnoea	Central neurogenic hyperventilation (midbrain lesion), metabolic encephalopathy
Cheyne-Stokes respiration	Deep cerebral lesions, metabolic encephalopathy (hyperpnoea alternating regularly with apnoea)
Apneustic breathing (an inspiratory pause)	Pontine lesions
Ataxic breathing (ataxic breathing normally progresses to agonal gasps and terminal apnoea)	Medullary lesions

Body Temperature in Coma

The presence of altered core body temperature is a useful aid in the diagnosis of coma. Hypothermia (<35°C) is frequently observed with alcohol intoxication, sepsis with shock, drowning, hypoglycaemia, myxoedema coma and exposure to cold. Severe hyperthermia may be seen in pontine haemorrhage, intra-cranial infections, heat stroke, serotonin syndrome, neuroleptic malignant syndrome and anticholinergic drug toxicity.

Recognition of Brain Herniation

Brain herniation syndromes (Fig. 59.1) occur when brain swelling or expansion of space-occupying lesions alters the structural relationships between brain tissue and fixed intracranial structures such as the falx cerebri or tentorium cerebelli. These syndromes may present with a characteristic constellation of clinical signs. Subfalcine herniation results from the lateral displacement of the cerebral hemisphere, as a result of an expanding mass lesion or unilateral brain swelling. It may present with non-specific clinical signs such as headache, nausea, vomiting and/or an altered level of consciousness. However, the displacement of the cingulate gyrus beneath the falx cerebri may also lead to compression of the ipsilateral anterior cerebral artery resulting in contralateral leg weakness. Mechanical compression of the dominant arcuate fasiculus may also result in receptive, expressive or conduction aphasia. [12] Expanding lesions in the intracranial compartment may also cause an inferolateral displacement of cerebral tissue. This displacement causes structures around the tentorium cerebelli to be compressed against this rigid structure. This herniation syndrome is accompanied by several characteristic clinical signs. Compression of the uncus of the temporal lobe against the tentorial incisura results in compression of the transiting third cranial nerve resulting in ipsilateral pupillary dilatation. Compression of the upper brainstem results in compression of the ascending reticular activating system (ARAS) resulting in progressive loss of consciousness. [13] Progression of this herniation syndrome leads to compression of medullary structures resulting in the Cushings response of decreased respiratory rate, hypertension and bradycardia. The final stages of this process are characterised by midbrain compression and dysfunction leading to decerebrate posturing and a loss of autonomic output clinically identified by fixed mid-sized pupils. [14] Tonsillar herniation is the protrusion of the cerebellar tonsils through the foramen magnum. In acute compressive herniation this may result in caudal medullary compression and obstruction of the fourth ventricle. However, it is important to note that tonsillar herniation is also seen as a congenital variant (Chiari malformation) and is not invariably a sign of a neurological emergency. Extracranial herniation results in the brain being displaced through a cranial defect, typically in post-surgical or post-traumatic settings. If excessive swelling occurs through a small defect, brain tissue may herniate with compression of cortical veins, leading to venous infarction and contusion. [15]



Extracranial hernia
Subfalcine hernia
Central DTH
Lateral DTH
Tonsillar hernia

The coronal anatomical illustration of the brain depicts various types of brain herniation. Labels include extracranial hernia, subfalcine hernia, central downward transtentorial hernia, lateral transtentorial hernia, and tonsillar hernia. Arrows show the direction of brain tissue displacement due to increased intracranial pressure. The cerebrum, cerebellum, and brainstem structures are visible, which illustrates how herniation compresses critical brain regions.

FIG. 59.1 Illustration of brain herniation syndromes that may occur as a result of brain swelling or expanding space-occupying lesions. *DTH* , descending transtentorial herniation .

Differentiating True Coma From Functional Coma

Functional coma, also described as psychogenic coma or unresponsiveness, is an involuntary coma-like state without an underlying structural or metabolic cause. Clinical features include eyelid fluttering when eyelashes are stroked, resisting passive eye opening, eyes rolling upwards and rapid eyelid closure. With the oculocephalic reflex, the eyes move concomitantly to head rotation, and with the oculovestibular reflex, they may wake up or demonstrate preservation of the fast component of nystagmus. Spontaneous eye movements are saccadic rather than slow roving movements. There may be a response to sudden external stimuli (e.g. blink to visual threat) but may also have a lack of response to painful stimuli. There may be active or varying resistance to passive motor testing. Spontaneous movement may be witnessed, particularly when observed from a distance rather than at the bedside. They may also demonstrate avoidance of ‘self-injury’, although injury can occur with profound functional impairment. The key clinical feature for differentiating functional disorders is the pattern of clinical abnormalities does not fit any specific neurological syndromes and/or is not in keeping with expected physiological response.

Initial Management of the Unconscious Patient

An altered level of consciousness is a cause for significant clinical concern. Initial management should focus on optimisation of physiological parameters, avoidance of factors that may exacerbate causative pathological processes and preparation to manage the patient in the event of further deterioration. Following these measures, prompt treatment of candidate pathologies, for example, the administration of broad-spectrum antibiotics to treat suspected meningoencephalitis should be commenced. It is important, however, to consider the risks and benefits of these interventions in the context of a broad differential diagnosis. Administration of aspirin for suspected ischaemic stroke for example may have profoundly negative implications in haemorrhagic stroke or sub-arachnoid haemorrhage. More definitive management should be guided by in-depth investigation and monitoring.

Specific Management for Patients with a Decreased Level of Consciousness

Airway Management

It is essential to rapidly ensure airway patency and determine the need for intubation based on a current conscious level, the trajectory of neurological function and the requirement for investigations or transfers which would present technical difficulties for airway instrumentation. Intubation should be planned and undertaken with the differential diagnosis in mind. Evidence of trauma, sudden onset headache or progressive obtundation in the context of a known space-occupying lesion should all raise the possibility of raised intra-cranial pressure. Symptoms and signs suggestive of vascular causes of neurological compromise should draw attention to the need for tight blood pressure control during intubation. Intubation strategies should focus on the use of potent opiates to avoid exaggerated sympathetic responses and rapid induction strategies to avoid hypercapnoea as this will exacerbate intra-cranial hypertension.

Respiratory Management

Respiratory function must be assessed to determine if it is adequate to maintain oxygenation and CO_2 excretion. Continuous monitoring consistent with the level of clinical concern for deterioration, for example, oxygen saturation monitoring in a mildly sedated patient, should be commenced. Decisions regarding the supplementation of inspired oxygen and native ventilation should be made in the context of the likely differential diagnosis. Patients suspected to have moderate to severe traumatic brain injury for example will require tight control of oxygen and CO_2 levels and there should be a low threshold for intubation, insertion of an arterial line and measurement of serial arterial blood gases.

Cardiovascular Management

Cardiovascular function must be assessed with a view to maintaining organ perfusion and cerebral blood flow. Intravenous access and blood pressure monitoring appropriate to the clinical context and likely patient trajectory should also be established. If there is a high probability that an acute vascular event is responsible for the altered conscious state, then blood pressure targets should be set accordingly. Targeting normotension (SBP >110 and <140 mm Hg) is a reasonable strategy until a definitive diagnosis can be determined.

Specific Interventions

If examination reveals signs of cerebral herniation and brain stem compression (obtundation, hypertension, bradycardia, unilateral or bilateral pupillary dilatation) intravenous 20% mannitol at a dose of 0.25–1 g/kg body weight should be administered, and urgent neurosurgical advice should be sought. 15a

Administration of 50% dextrose should be commenced in the context of hypoglycaemic coma. Co-administration of IV thiamine should also be considered to prevent the precipitation of Wernicke's encephalopathy.

The administration of IV naloxone should be considered in the context of a suspected narcotic overdose with impending respiratory arrest. In the event of marked clinical improvement post naloxone the short half-life of naloxone relative to that of many opiate medications represents a risk of recurrent deterioration. Further naloxone doses or a naloxone infusion should be considered. Consideration can be given to the use of flumazenil with suspected benzodiazepine overdose, although caution should be exercised, as its use may precipitate seizures in those with a known seizure disorder or benzodiazepine dependence.

Suspected meningoencephalitis should be treated with broad-spectrum CSF penetrating antibiotics even if cerebrospinal fluid results are not available. A combination of benzylpenicillin and ceftriaxone is usually recommended for a community-acquired bacterial meningitis, and aciclovir for viral encephalitis. Suspected seizures should be treated emergently as outlined in Chapter 61: Status Epilepticus. Extremes of body temperature should be recognised and treated with the initial aim of normothermia.

Routine Investigations

Standard blood tests include a full blood count, renal and liver function tests and arterial blood gas which includes a measure of serum glucose. In suspected drug overdose a toxicology screen for alcohol, paracetamol, salicylates, benzodiazepines and tricyclic antidepressants should be performed. Serum osmolality should be measured, and a sample of serum should be stored for later analysis for uncommon drug ingestions.

CNS Biomarkers

A number of biomarkers of brain injury have been evaluated as predictors of the severity of the brain injury and to assist with prognosis/triage, from both traumatic [16] and non-traumatic aetiologies. [17] These include neuron-specific enolase (cytoplasm of neurons), S-100B protein (astroglial cells), CK-BB fraction (astrocytes), ubiquitin C-terminal hydrolase L1 (UCH-L1), glial fibrillary acidic protein (GFAP) (glial origin), calpain and caspase. GFAP is emerging as a particularly promising biomarker for the identification of TBI, ischaemic and haemorrhagic stroke. [18] Recent evidence also shows that both GFAP and UCH-L1 levels measured on the day of injury have significant prognostic utility in moderate to severe TBI. [19]

Lumbar Puncture

Lumbar puncture (LP) is used to diagnose intra-cranial infection and identify causative organisms. It may also detect abnormal cytology in cases of suspected malignant meningeal infiltration. CSF sampling can also be used to exclude a diagnosis of SAH although the increasing use of high-resolution computed tomography (CT) scans has increased confidence in radiological exclusion of SAH. [20] Some of the commonly reported complications post-LP include post-puncture headache (12%–39%) and traumatic tap (15%–20%). Brain herniation is a rare potential complication seen with conditions associated with raised intracranial pressure due to a space-occupying lesion, and LP should only be undertaken after appropriate imaging to exclude this scenario.

Neuroimaging

Computed Tomography Scan

The most commonly used radiological investigation for evaluation of the comatose patient is CT scanning of the brain. CT scanning is a low-cost, high-yield investigation which can be performed rapidly on unstable patients. CT imaging can detect trauma, SAH and intracerebral haemorrhage, haemorrhagic and non-haemorrhagic strokes, cerebral oedema, hydrocephalus and the presence of a space-occupying lesion. Disadvantages of CT scanning include the requirement to transport the patient away from areas dedicated to acute clinical care, low sensitivity to acute ischaemic stroke, brainstem lesions and soft tissue injuries of the cervical spine and patient exposure to ionising radiation.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) scans provide superior resolution of the grey and white matter compared to CT scans. MRI is more sensitive than CT for the detection of acute ischaemia, diffuse axonal injury and cerebral oedema, tumour and abscess. Brainstem and posterior fossa structures are visualised with much greater accuracy and resolution. MRI does not involve exposure to ionising radiation. Disadvantages of MRI include long imaging time frames, requirement for specific personnel and expertise, and the risk of iatrogenic injury from unidentified ferromagnetic items in proximity to the scanner.

Neurophysiological Investigations in Disorders of Consciousness

Electroencephalography (EEG) monitoring and somatosensory evoked potentials (SSEP) are also used to investigate causes of disordered consciousness and inform neuroprognostication. They are discussed in greater detail in Chapter 64 .

Management of Specific Sub-Types of Disorders of Consciousness

Many of the pathologies that result in decreased consciousness are discussed in dedicated chapters of this text. However, several pathologies are primarily defined by their impact on consciousness and require detailed discussion in this context.

Anoxic Coma/Encephalopathy

Cardiac arrest is a common cause of coma resulting in ICU admission. The symptomatology and clinical outcome of patients with anoxic brain damage depend on the severity and duration of oxygen deprivation to the brain.

Management strategies for hypoxic encephalopathy have undergone significant change in line with successive trials of therapeutic hypothermia. Initial studies identified outcome benefits with the use of therapeutic hypothermia; body temperature of 32–34°C post-cardiac arrest,[16], [21] and changed practice significantly. They were, however, subject to criticism for a lack of statistical power. Subsequent larger studies failed to show the benefit of cooling to 33°C over mild hypothermia of 36°C[22] and a recent well-designed, adequately powered trial has shown no benefit of mild hypothermia (36°C) over avoidance of hyperthermia.[23] As such, it appears that the outcome benefits identified in initial trials may have resulted from the avoidance of hyperthermia, and potentially use of strict sedation protocols, rather than aggressive cooling strategies *per se* . The negative side effects associated with hypothermia such as bradycardia and immunosuppression likely contribute to this lack of benefit and there is an emerging consensus that therapeutic hypothermia is no longer indicated and should be replaced by a period of avoidance of hyperthermia. This change is reflected in the most recent European Resuscitation Council and European Society of Intensive Care Medicine (ERC-ESICM) guidelines. [24]

Some patients with suspected hypoxic encephalopathy recover neurological function rapidly, whereas a significant proportion display delayed neurological recovery of a varying degree and a further sub-group shows no meaningful neurological recovery. Neuroprognostication is undertaken in an attempt to inform treatment decisions and avoid unnecessary treatment in patients who will not survive. Whilst neuroprognostication guidelines assist in predicting poor outcomes, it is essential to consider the patient's pre-existing functional status and previously stated wishes regarding resuscitation, long-term care and acceptable outcomes. Decision making around the continuation or withdrawal of organ-support modalities should always seek to be in accordance with the previously understood wishes of the patient.

No single clinical predictor of neurological outcome is completely accurate, and neuroprognostication should utilise a multimodal strategy, including clinical examination, neurophysiological investigations, imaging and biomarkers. Whilst the optimal time for prognostication is unclear, it is generally recommended to occur at least 72 hours post return of spontaneous circulation (ROSC). It is also essential to minimise the influence of factors that may confound accurate prognostication such as residual sedation, neuromuscular blocking agents and metabolic derangements.

The European Resuscitation Council and European Society of Intensive Care Medicine proposed guidelines in 2021, [25] updating their prognostication strategy algorithm from 2015, for the comatose patient with a GCS motor score of 3 or less at 72 hours or more from ROSC. In the absence of confounders, poor outcome is considered likely when two or more of the following predictors are present:

- No pupillary and corneal reflexes ≥72 hours
- Bilaterally absent N20 SSEP at ≥24 hours
- Highly malignant EEG (suppressed background, burst suppression) at >24 hours (based on American Clinical Neurophysiology Society 2021 EEG terminology)

- Status myoclonus within 72 hours
- Diffuse and extensive anoxic injury on brain CT or MRI
- Neuron-specific enolase levels >60 µg/L at 48 hours and/or 72 hours

A 2022 systematic review [26] of predictors of a *good* neurological outcome in comatose adult survivors of cardiac arrest included 37 studies and identified the following indicators:

- GCS motor score 4 or 5 immediately or at 72–96 hours after ROSC
- SSEP N20 wave amplitude above 4 µV within 72 hours from ROSC
- Continuous EEG background without discharges within 72 h from ROSC
- Absent diffusion restriction in cortex or grey matter on MRI on days 2–7 after ROSC
- Normal neuron-specific enolase levels at 24–72 hours after ROSC

Similarly, a 2023 guideline [27] based on a narrative systematic review of the literature identified predictors of poor outcomes divided into reliable and moderate value for comatose patients where the clinical picture is consistent with a severe and widespread brain injury. Reliable predictors included absent pupillary responses bilaterally >72 hours following ROSC and/or bilateral absence of N20 waves on SSEP >48 hours from ROSC. Moderate predictors included CT >48 hours from ROSC with diffuse pattern of loss of grey-white differentiation and sulcal effacement, MRI DWI sequence 2–7 days from ROSC with diffuse pattern of restricted diffusion, and EEG with background suppression or burst suppression >72 hours from ROSC and rewarming.

The Confused/Encephalopathic Patient in the Intensive Care Unit

Encephalopathy is a term used to describe the alteration in the level or content of consciousness. Metabolic encephalopathy, particularly of septic aetiology, is the most common cause of altered mental status in the ICU setting.[28] A number of processes can lead to metabolic encephalopathy as summarised in Box 59.4 . A number of features in the history and examination help to differentiate metabolic from structural causes of altered conscious states (Table 59.4).

Box 59.4

Aetiology of metabolic/toxic encephalopathy

Hepatic failure
Renal failure
Respiratory failure
Sepsis
Electrolyte abnormalities: Hyponatraemia, hypernatraemia, hypercalcaemia
Hypoglycaemia and hyperglycaemia
Acute pancreatitis
Endocrine: Addisonian crisis, myxoedema coma, thyroid storm
Drug withdrawal: Benzodiazepine, opiates
Hyperthermia
Toxins: Alcohols, glycols, tricyclic antidepressants

Table 59.4

Distinguishing features of structural and metabolic encephalopathy

FEATURE	STRUCTURAL	METABOLIC
State of consciousness	Usually fixed level of depressed conscious state, may deteriorate progressively	Milder alteration of conscious state, waxing and waning of altered sensorium
Fundoscopy	May be abnormal	Usually normal
Pupils	May be abnormal, either in size or response to light	Usually preserved light response (although pupil shape and reactivity affected in certain overdoses – see above)
Eye movements	May be affected	Usually preserved
Motor findings	Asymmetrical involvement	Abnormalities usually symmetrical
Involuntary movements	Not common	Asterixis, tremor, myoclonus frequently seen

From Plum F. Sustained impairment of consciousness. In: Bennett C, ed. *Cecil Textbook of Medicine* . Philadelphia, PA: W.B. Saunders; 1996:1970–1978.

Septic encephalopathy and ICU syndrome are complex encephalopathies with multi-factorial aetiologies. They occur frequently in the ICU context.
